1 Agentic RAG — Zero to Hero

Build a production-style RAG assistant over ArXiv ML/AI papers with progressive architectures, reproducible artifacts, and measured outputs.

Current reference scope is **4,000 papers**, with **legacy 600-paper** results preserved for comparison.

1.1 Start Here

- Project overview: [What Is This Project](#)
- Setup requirements: [Prerequisites](#)
- Environment setup: [Installation](#)
- Guided routes: [Learning Tracks](#)
- Full notebook map: [Tutorial Index](#)
- Download handbook: [Full Tutorial PDF](#)

1.2 Learning Path

Part	Notebook(s)	Focus
Part 1	<code>01_naive_rag.ipynb</code>	Dense FAISS baseline and evaluation
Part 2	<code>02_advanced_rag.ipynb</code>	BM25 + hybrid fusion + reranking
Part 3	<code>03_agentic_rag_langgraph.ipynb</code>	LangGraph CRAG control loop
Part 4	<code>04_graph_rag.ipynb</code>	GraphRAG variants (ChromaDB/Pinecone/agentic graph)
Part 5	<code>05_hybrid_rag.ipynb</code> to <code>09_multimodal_rag.ipynb</code>	Five standalone advanced techniques

1.3 Runtime Model

1.3.1 Fully local core path

- Embeddings and generation run locally via Ollama.
- Parts 1-3 and Part 5 can run without cloud dependencies.

1.3.2 Optional cloud path

- Part 4 includes a Pinecone backend option.
 - Pinecone execution requires valid Pinecone credentials.
-

1.4 Two Reader Paths

1.4.1 Student path

1. [Learning Tracks](#)
2. [Tutorial Index](#)
3. Part 1 → Part 5 chapters in order

1.4.2 Recruiter path

1. [Recruiter Brief](#)
 2. [Full Benchmark Table](#)
 3. [Claims Traceability](#)
 4. [Full Tutorial PDF](#)
-

1.5 Result Sources

- Current baseline metrics: `artifacts/eval_results/*_4000.json`
- Legacy reference metrics: `artifacts/eval_results/legacy_600/*.json`
- Part 5 metrics: `artifacts/rag_v2/*/*.json`

For interpretation guidance, use: - [Full Benchmark Table](#) - [Reading the Numbers Honestly](#) - [Recruiter Brief](#)

2 Getting Started

What Is This Project?

Before running a single cell, it's worth understanding *why* this project exists and what problem it actually solves. This page gives you the full picture: the problem with LLMs, why RAG is the standard fix, why this particular corpus was chosen, and what makes this tutorial different from the dozens of others out there.

The problem: LLMs are confident, but frozen and fallible

Large language models are impressive. Ask `granite4.1:8b` about transformer attention mechanisms, and it will give you a fluent, detailed answer. But that answer has two fundamental problems.

Problem 1 — The knowledge cutoff. Every LLM was trained on data up to a certain date. Anything published after that date — a new paper, a new model, a new technique — simply doesn't exist in the model's world. For a field like machine learning, where the landscape changes every few months, a frozen knowledge base is a serious limitation.

Problem 2 — Hallucination. LLMs generate the most *statistically probable* next token given their training data. When a question touches something they don't know well, they don't say "I don't know" — they generate a plausible-sounding answer anyway. This is called *hallucination*, and it's not a bug that will be patched — it's a structural feature of how autoregressive language models work.

Why hallucination matters for research

If you're using an LLM to answer questions about recent ML papers, the model will sometimes fabricate paper titles, invent author names, or confidently describe results that don't exist. This is dangerous precisely *because* the answer sounds authoritative.

The solution: RAG grounds the answer in real documents

Retrieval-Augmented Generation (RAG) is the standard architectural pattern for fixing both problems at once. The core idea is simple:

Before the LLM generates an answer, *retrieve* the relevant documents from a knowledge base and *inject* them into the prompt. Instruct the model to answer only from those documents.

When you do this, the model's answer is *grounded* — every claim it makes is constrained to the content you gave it. If the answer tries to go beyond the documents, you can detect that (which Part 3 of this tutorial does automatically).

A RAG pipeline has two phases:

1. **Indexing (offline):** Load your documents, split them into chunks, embed each chunk as a vector, store the vectors in a searchable index.

2. **Querying (online):** When a question arrives, embed the question, search the index for the most similar chunks, inject those chunks into the LLM prompt, generate an answer.

This tutorial builds both phases, from scratch, step by step.

Why ArXiv ML/AI papers?

The current baseline corpus is 4,000 ArXiv ML/AI paper abstracts from HuggingFace (`ccdv/arxiv-summarization`, ML-filtered). Historical 600-paper runs are preserved as legacy comparison artifacts.

This is an unusual choice for a tutorial — most use Wikipedia articles or random web pages. Here's why ArXiv ML papers are better for learning RAG:

Self-referential. We're building a RAG system *about* RAG systems, transformers, and fine-tuning. The system can answer questions about itself. This makes it easy to spot when retrieval is working (you'll recognise the papers it finds) and when it's failing (you'll notice when it retrieves something irrelevant).

Verifiable. ArXiv papers have titles, abstracts, and well-defined claims. A good answer is clearly good; a bad answer is clearly bad. This makes evaluation honest rather than subjective.

Naturally multi-topic. A question like "how does LoRA relate to quantization?" genuinely requires finding information across multiple papers. This exposes the real challenges of retrieval — not just "find the paper about X" but "find all the papers that together answer the question."

Terminology-dense. ML papers are full of exact technical terms — model names, method names, benchmark names. This is the ideal stress test for the hybrid retrieval system in Part 2, where keyword-based BM25 search handles exact terms that semantic search sometimes misses.

The progression: Naive → Advanced → Agentic → GraphRAG → New Techniques

This tutorial is structured as five progressively more capable tracks. Each one fixes the failures of the previous one.

Part 1 — Naive RAG: The baseline

The simplest possible RAG pipeline: embed everything with one model, search with FAISS, generate with the LLM. It works, but the retrieval quality is poor. When measured honestly against 20 diverse queries, it achieves an MRR of 0.299 — meaning the most relevant paper appears at rank 3–4 on average.

You'll see exactly *why* it fails: semantic search alone misses queries that use exact technical terminology, and there's no way to recover once the wrong documents are retrieved.

Part 2 — Advanced RAG: Better retrieval

Part 2 adds three improvements to the retrieval layer:

- **BM25 keyword search** — catches exact technical terms that semantic search misses
- **Hybrid retrieval** — combines BM25 and dense scores into a single ranked list
- **Cross-encoder reranking** — re-scores the top candidates with a more accurate model

The result: MRR jumps to 0.441 — a 47% improvement over the naive baseline, with the same LLM and the same corpus. The lesson is that *retrieval quality is the biggest lever in a RAG system*, not the LLM.

Part 3 — Agentic RAG: Self-correction

Part 3 adds intelligence on top of the Advanced RAG retriever. Instead of blindly generating from whatever was retrieved, the system:

1. **Grades the retrieved documents** — asks the LLM "are these relevant?"
2. **Falls back to web search** — if no relevant documents are found in the corpus
3. **Grades its own answer** — checks whether the answer contains only claims from the retrieved documents
4. **Retries** — if a hallucination is detected, regenerates the answer (up to twice)

This is the CRAG architecture (Corrective RAG, Yan et al. 2024), implemented as a LangGraph state machine with conditional routing. Legacy 10-query runs showed strong local-corpus coverage, while current 4,000-baseline artifacts also expose the tradeoff between faithfulness and fallback behavior under harder queries.

Part 4 — GraphRAG: Structured retrieval at scale

Part 4 adds entity extraction, knowledge-graph construction, community detection, and dual backend execution (ChromaDB + Pinecone), then wraps GraphRAG in an agentic LangGraph loop. This introduces multi-hop and community-level retrieval strategies that are harder to express in a pure chunk-similarity pipeline.

Part 5 — New techniques: focused standalone implementations

Part 5 adds five additional implementations as isolated, production-style modules and notebooks:

- Hybrid RAG
- GraphRAG
- Agentic RAG
- Corrective RAG (CRAG)
- Multimodal RAG (including OCR and vision branches)

These runs are tracked under `artifacts/rag_v2/` and documented in `docs/09_part5_new_techniques/`.

What makes this tutorial different?

Most RAG tutorials show you *how to build* the pipeline but not *how well it works*. They use 5 hand-picked test questions and don't measure anything. They don't explain why certain design choices were made, or what happens when something fails.

This tutorial does things differently:

- **Every step is measured.** Retrieval quality is evaluated with benchmarked metrics and persisted JSON artifacts at both legacy 600 and current 4,000 scale.
- **The eval is honest.** Legacy 600 numbers are kept visible, and current 4,000 numbers are reported side-by-side so readers can compare scaling effects directly.
- **Failures are explained.** When hybrid search with alpha-blending doesn't beat BM25 alone, the tutorial explains why rather than hiding the result.
- **Local-first with optional cloud backend.** The core path runs locally with Ollama. Part 4 also includes an optional Pinecone backend that requires valid credentials.

Ready to check whether your machine is set up? Continue to [Prerequisites](#).

Prerequisites

This page tells you exactly what you need — in terms of knowledge, tools, and hardware — before you open the first notebook. Nothing here is aspirational; these are the actual requirements tested on the machine where this project was built.

Knowledge prerequisites

You do **not** need prior experience with RAG, LangChain, LangGraph, FAISS, or BM25. All of these are explained from scratch.

Here is what you *do* need:

Concept	Level required	Why it matters
Python — functions, classes, dicts, list comprehensions	Comfortable writing it	All code is Python
NumPy arrays	<code>np.array([1, 2, 3])</code> level is enough	Embeddings are float arrays
What an API call is (send a request, get a response)	Basic familiarity	We call the local Ollama REST API
What a neural network does at a high level	"maps input → output" is sufficient	Understanding embeddings and LLMs
Terminal, file paths, Git	Basic navigation	Installation and running notebooks

You do **not** need:

- Linear algebra beyond understanding that dot product $\approx$ similarity
- Transformer architecture internals or attention math
- Prior LangChain or LangGraph experience
- Cloud accounts of any kind
- A formal ML or CS background

**If you're fuzzy on embeddings**

The Core Concepts section covers [Embeddings & Similarity](#) in detail before you encounter them in the notebooks. Read that page if the word "embedding" feels vague — you don't need to understand it before starting, but knowing the intuition early will make the notebook cells click faster.

Tool prerequisites

1. Ollama

Ollama is the local model runtime. It downloads LLM and embedding models, manages GPU memory, and exposes a simple REST API at `http://localhost:11434`. You talk to it the same way you'd talk to OpenAI's API — but everything stays on your machine.

Install Ollama:

```
curl -fsSL https://ollama.com/install.sh | sh
```

Verify it's working:

```
ollama --version  
# ollama version is 0.4.7
```

2. Pull the models

Once Ollama is installed, pull the core models first. These are required for the main text RAG path:

```
# Embedding model - used in the core text-RAG notebooks  
ollama pull qwen3-embedding:0.6b # ~639 MB  
  
# LLM - used for answer generation and LLM-as-judge grading  
ollama pull granite4.1:8b # ~5.3 GB
```

Optional models used in extended notebooks:

```
# Higher-capacity embedding variant used in some experiments  
ollama pull qwen3-embedding:4b  
  
# Multimodal notebook (Part 5)  
ollama pull qwen3.5:4b  
ollama pull glm-ocr
```

What these models do

`qwen3-embedding:0.6b` converts text into a 1024-dimensional vector. It's a lighter version of the full `qwen3-embedding:4b` model — same architecture, lower VRAM, slightly lower retrieval quality. The tutorial uses the 0.6b variant by default to fit on 6 GB VRAM cards.

`granite4.1:8b` is IBM's instruction-tuned LLM optimised for RAG, structured JSON output, and tool use. It serves as both the answer generator and the judge that grades retrieved documents and generated answers.

The downloads are one-time. After `ollama pull`, the models are cached locally at `~/.ollama/models/`.

Verify the pulls completed:

```
ollama list
# NAME                ID                SIZE    MODIFIED
# granite4.1:8b        ...              5.3 GB   ...
# qwen3-embedding:0.6b ...              639 MB   ...
```

3. Python 3.13

The project is tested on Python 3.13.13. Python 3.12.10 also works.

The recommended way to manage Python versions in this project is `uv` (see below). You do not need to pre-install Python 3.13 separately — `uv` will download it for you.

4. uv

`uv` is a Python package manager written in Rust. It replaces `pip`, `virtualenv`, and `pyenv` with a single tool that is orders of magnitude faster than `pip`.

Install uv:

```
curl -LsSf https://astral.sh/uv/install.sh | sh
```

Verify:

```
uv --version
# uv 0.11.19 (or later)
```

Why uv instead of pip?

With `pip`, creating a virtual environment and installing the full dependency list for this project takes 3–5 minutes. With `uv`, it takes under 30 seconds. More importantly, `uv python install` lets you pin an exact Python version without needing `pyenv` or `conda` — which keeps the environment reproducible across machines.

5. Chrome/Chromium (optional, for PDF export)

If you want to regenerate the full tutorial handbook PDF locally, you need a Chrome/Chromium binary available in `PATH`.

Verify:

```
google-chrome --version
```

If this command is unavailable, install Chrome/Chromium from your distro package manager before running `scripts/build_tutorial_pdf.py`.

Hardware requirements

This project was developed and tested on the following hardware. All model VRAM figures are from actual runs.

Component	Tested configuration	Minimum
GPU	NVIDIA RTX 4060 Laptop (8 GB VRAM)	Any GPU with ≥ 6 GB VRAM
RAM	16 GB	8 GB (tight; FAISS index + Python overhead)
Storage	~12 GB free	~12 GB (models ~8 GB, <code>.venv</code> ~3 GB, index ~70 MB, data ~300 MB)
CUDA	12.8	12.x (Ollama manages its own CUDA build)

VRAM usage breakdown:

Ollama loads one model at a time and unloads it after 5 minutes of inactivity. The embedding model and the LLM are never in VRAM simultaneously during normal execution.

Phase	Model active	VRAM used
Indexing (notebook 01)	<code>qwen3-embedding:0.6b</code>	~639 MB
LLM generation / grading	<code>granite4.1:8b</code>	~5.3 GB
Reranker inference (notebook 02)	CPU only	0 GB

Phase	Model active	VRAM used
Peak (single model)	granite4.1:8b	~5.3 GB

CPU-only fallback

Ollama supports CPU-only inference. If you don't have a compatible GPU, everything will still work – but `granite4.1:8b` generation will be 10–20× slower (expect 30–60 seconds per answer instead of 3–5 seconds). The embedding step in notebook 01 (~2100 chunks) will take 15–20 minutes on CPU instead of ~2 minutes on GPU.

If you're on CPU and want faster iteration, consider `phi4-mini:3.8b` as a lighter LLM alternative – pull it with `ollama pull phi4-mini:3.8b` and swap the model name in the relevant cells.

Software versions (for reference)

These are the exact versions in the tested environment. The `requirements.txt` file pins all of these.

Package	Version
Python	3.13.13
LangGraph	0.4.8
LangChain	0.3.25
FAISS (CPU)	1.11.0
rank-bm25	0.2.2
sentence-transformers	4.1.0
datasets (HuggingFace)	3.6.0
ollama (Python client)	latest
uv	0.11.19

Once Ollama is installed, the models are pulled, and uv is ready, you have everything you need. Continue to [Installation](#).

Installation

This page takes you from fresh clone to runnable notebook environment.

If Ollama and required models are not installed yet, complete [Prerequisites](#) first.

1) Clone repository

```
git clone https://github.com/pypi-ahmad/agentic-rag-arxiv-research-assistant.git
cd agentic-rag-arxiv-research-assistant
```

2) Pull required Ollama models

```
ollama pull qwen3-embedding:0.6b
ollama pull granite4.1:8b
```

Optional models used in extended notebooks:

```
ollama pull qwen3-embedding:4b
ollama pull qwen3.5:4b
ollama pull glm-ocr
```

Verify:

```
ollama list
```

3) Create Python environment with `uv`

```
uv python install 3.13.13
uv venv --python 3.13.13
source .venv/bin/activate
```

4) Install dependencies

```
uv pip install -r requirements.txt
```

Quick check:

```
python --version
uv pip list | grep -E "faiss|langgraph|rank-bm25"
```

5) Register Jupyter kernel

```
.venv/bin/python -m ipykernel install --user --name agentic-rag-env --display-name "Agentic RAG"
```

6) Launch Jupyter

```
jupyter notebook
```

Open `notebooks/01_naive_rag.ipynb` and select the `Agentic RAG` kernel.

7) (Optional) Build full tutorial PDF

```
uv run python scripts/build_tutorial_pdf.py
```

Output:

```
docs/assets/agentic-rag-full-tutorial.pdf
```

Minimal smoke test cell

```
import sys
import faiss
import ollama

print("Python:", sys.version.split()[0])
print("FAISS:", faiss.__version__)

models = [m.model for m in ollama.list().models]
print("Models:", models)

assert any("qwen3-embedding" in m for m in models), "Missing qwen3-embedding model"
assert any("granite4.1:8b" in m for m in models), "Missing granite4.1:8b model"
print("Setup OK")
```

Repository structure (high-level)

```
agentic-rag-arxiv-research-assistant/  
├─ notebooks/           # 01-09 tutorial notebooks  
├─ src/                 # shared pipeline modules + rag_v2 modules  
├─ artifacts/           # metrics/results/indexes/traces  
├─ docs/                # MkDocs tutorial documentation  
├─ requirements.txt  
└─ mkdocs.yml
```

Committed vs generated artifacts

- Committed: benchmark JSONs and reference outputs used by docs.
- Generated during runs: many runtime artifacts (for example FAISS binaries, notebook-specific outputs, backend-specific files).
- `artifacts/faiss_index/` is ignored in git and regenerated by running notebook 01.

Continue to [How to Use This Tutorial](#) and [Tutorial Index](#).

How to Use This Tutorial

This tutorial is notebook-first and dependency-aware.

Rule 1: Follow the execution order

Run notebooks in this order:

```
01_naive_rag.ipynb
→ 02_advanced_rag.ipynb
→ 03_agentic_rag_langgraph.ipynb
→ 04_graph_rag.ipynb
→ 05_hybrid_rag.ipynb
→ 06_graphrag.ipynb
→ 07_agentic_rag.ipynb
→ 08_crag.ipynb
→ 09_multimodal_rag.ipynb
```

Rule 2: Understand hard dependencies

- Notebook 01 builds shared FAISS/chunk artifacts:
- `artifacts/faiss_index/index.bin`
- `artifacts/faiss_index/chunks.pkl`
- Notebooks 02 and 03 load these files at startup.
- Part 5 notebooks (05 - 09) are isolated technique implementations under `src/rag_v2/` and `artifacts/rag_v2/`.

If notebook 02 or 03 fails with FAISS file-not-found, rerun notebook 01 fully.

Notebook map

Notebook	What it does	Main outputs
<code>01_naive_rag.ipynb</code>	Build baseline dense RAG index and eval	<code>artifacts/faiss_index/*</code> , <code>artifacts/eval_results/01_naive_rag_4000.json</code>
<code>02_advanced_rag.ipynb</code>	BM25/hybrid/reranking evaluation	<code>artifacts/eval_results/02_advanced_rag_4000.json</code>

Notebook	What it does	Main outputs
<code>03_agentic_rag_langgraph.ipynb</code>	LangGraph CRAG evaluation	<code>artifacts/eval_results/03_agentic_rag_4000.json</code> , <code>traces</code>
<code>04_graph_rag.ipynb</code>	GraphRAG variant evaluations	runtime-generated <code>04*_graphrag_4000.json</code>
<code>05_hybrid_rag.ipynb</code>	Part 5 Hybrid RAG implementation	<code>artifacts/rag_v2/hybrid/05_hybrid_metrics.json</code>
<code>06_graphrag.ipynb</code>	Part 5 GraphRAG implementation	<code>artifacts/rag_v2/graphrag/06_graphrag_metrics.json</code>
<code>07_agentic_rag.ipynb</code>	Part 5 Agentic RAG implementation	<code>artifacts/rag_v2/agentic/07_agentic_metrics.json</code>
<code>08_crag.ipynb</code>	Part 5 Corrective RAG implementation	<code>artifacts/rag_v2/crag/08_crag_metrics.json</code>
<code>09_multimodal_rag.ipynb</code>	Part 5 Multimodal RAG implementation	<code>artifacts/rag_v2/multimodal/09_multimodal_metrics.json</code>

How docs and notebooks connect

- Docs explain design choices, failure modes, and interpretation.
- Notebooks are runnable execution artifacts.
- Use docs pages to understand why a metric or behavior changed, then verify in notebook outputs.

For full navigation across all tracks, see [Tutorial Index](#). For route selection, see [Learning Tracks](#). For offline reading, see [Full Tutorial PDF](#).

Learning Tracks

Use the track that matches your goal and available time.

Track 1 — Fast Foundations (2-3 hours)

Best for first-time RAG learners who want working intuition quickly.

1. Read [What Is This Project](#)
2. Complete [Installation](#)
3. Run `01_naive_rag.ipynb`
4. Run `02_advanced_rag.ipynb`
5. Read [Reading the Numbers Honestly](#)

Expected outcome: - Understand dense vs sparse vs hybrid retrieval - Know how to read Recall@5, Precision@5, and MRR - Reproduce baseline metrics from committed artifacts

Track 2 — Full Zero-to-Hero (8-12 hours)

Best for serious learning and portfolio-level understanding.

1. Follow [Tutorial Index](#) in order
2. Run all nine notebooks (or inspect the executed notebook copies in the `notebooks/` folder)
3. Read each corresponding chapter under `docs/03_*` to `docs/09_*`
4. Compare 4,000 baseline vs legacy 600 baseline artifacts
5. Study [All 5 Improvements Explained](#)

Expected outcome: - End-to-end understanding of modern RAG variants - Ability to explain tradeoffs (latency, quality, complexity) - Evidence-backed project story for interviews

Track 3 — Recruiter / Interview Review (45-90 minutes)

Best when you need a quick but credible project walkthrough.

1. Read [Recruiter Brief](#)
2. Verify key numbers in [Full Benchmark Table](#)
3. Confirm evidence mapping in [Claims Traceability](#)

4. Download [Full Tutorial PDF](#)

Expected outcome: - Clear architecture and decision narrative - Metric claims tied to concrete artifacts - Interview-ready explanation of what was built and measured

Recommended Runtime Profiles

Profile	Use when	Minimum path
Local-only	No cloud credentials available	Parts 1-3 + Part 5 notebooks
Hybrid local + cloud	Pinecone evaluation is needed	Add Part 4 Pinecone variant

Quality and Verification Commands

```
uv run python scripts/check_docs_integrity.py
uv run python scripts/check_docs_facts.py
uv run mkdocs build --strict
```

Tutorial Index

This is the canonical index for the end-to-end tutorial track.

Use this page to decide notebook order, dependencies, and where outputs are written.

For guided routes, see [Learning Tracks](#). For offline study, see [Full Tutorial PDF](#).

Recommended Execution Order

1. `notebooks/01_naive_rag.ipynb`
2. `notebooks/02_advanced_rag.ipynb`
3. `notebooks/03_agentic_rag_langgraph.ipynb`
4. `notebooks/04_graph_rag.ipynb`
5. `notebooks/05_hybrid_rag.ipynb`
6. `notebooks/06_graphrag.ipynb`
7. `notebooks/07_agentic_rag.ipynb`
8. `notebooks/08_crag.ipynb`
9. `notebooks/09_multimodal_rag.ipynb`

Notebook Matrix

Notebook	Technique	Depends on	Primary outputs	Docs chapter
<code>01_naive_rag.ipynb</code>	Naive dense RAG	none	<code>artifacts/faiss_index/index.bin</code> , <code>artifacts/faiss_index/chunks.pkl</code> , <code>artifacts/eval_results/01_naive_rag_4000.json</code>	<code>docs/03_part1_naive_rag/</code>
<code>02_advanced_rag.ipynb</code>	BM25 + hybrid + reranking	FAISS/chunks from NB01	<code>artifacts/eval_results/02_advanced_rag_4000.json</code> , retrieval plots in <code>artifacts/eval_results/</code>	<code>docs/04_part2_advanced_rag/</code>

Notebook	Technique	Depends on	Primary outputs	Docs chapter
03_agentic_rag_langgraph.ipynb	LangGraph CRAG (legacy track)	FAISS/chunks from NB01	artifacts/eval_results/03_agentic_rag_4000.json , traces in artifacts/agent_traces/	docs/05_part3_agentic_rag/
04_graph_rag.ipynb	GraphRAG (ChromaDB, Pinecone, agentic graph)	corpus and runtime backends	runtime-generated 04_*_graphrag_4000.json files under artifacts/eval_results/	docs/06_part4_graph_rag/
05_hybrid_rag.ipynb	Part 5 Hybrid RAG	prior project corpus/index assets	artifacts/rag_v2/hybrid/05_hybrid_metrics.json	docs/09_part5_new_techniques/hybrid_rag.md

Model Requirements by Path

Core models

```
ollama pull qwen3-embedding:0.6b  
ollama pull granite4.1:8b
```

Optional/extended models

```
ollama pull qwen3-embedding:4b  
ollama pull qwen3.5:4b  
ollama pull glm-ocr
```

Dual-Baseline Guidance

- Treat 4,000-paper outputs as the current baseline.
- Keep 600-paper outputs as historical reference for scale comparison.
- Do not compare metrics across differently scoped eval settings without noting the scope.

Validation Commands

```
uv run python scripts/check_docs_integrity.py  
uv run python scripts/check_docs_facts.py  
uv run mkdocs build --strict
```

Full Tutorial PDF

This repository ships a full handbook PDF for offline learning and recruiter review.

Download

- [agentic-rag-full-tutorial.pdf](#)

Rebuild Locally

```
uv run python scripts/build_tutorial_pdf.py
```

The script builds docs in strict mode, renders the print page, and writes:

- `docs/assets/agentic-rag-full-tutorial.pdf`

Notes

- The PDF is generated from the MkDocs content, so markdown pages remain the single source of truth.
- If dependencies are missing, install with:

```
uv pip install -r requirements.txt
```

The renderer uses a local Chrome/Chromium binary in headless mode.

3 Core Concepts

What Is RAG?

Before we write a single line of retrieval code, we need to understand *why* RAG exists. The answer starts with two uncomfortable truths about large language models.

The Two Problems RAG Solves

Problem 1 – LLMs Hallucinate

Ask a language model a question it does not know the answer to and it will not say "I don't know." It will invent a plausible-sounding answer, cite papers that do not exist, and deliver the whole thing with complete confidence.

This is not a bug to be fixed in the next version. It is a structural property of how these models work. An LLM learns to predict the next token given everything that came before. When no correct token is strongly favoured by training, the model still has to output *something* – and it picks whatever is statistically plausible in that context. The model has no internal alarm that fires when it is making something up.

Why the confident tone?

Training data contains authoritative text – textbooks, Wikipedia, academic papers. The model learns that confident, declarative sentences are common in these sources. So when it generates freely, it naturally produces confident-sounding text, even when the content is fabricated.

Problem 2 – LLMs Have a Knowledge Cutoff

Every LLM is trained on a snapshot of the internet up to a certain date. GPT-4's training data ends in early 2024. Claude's ends in early 2025. Any paper published after that date simply does not exist as far as the model is concerned. Ask it about a technique introduced last month and it either admits ignorance or – worse – confabulates an answer based on adjacent knowledge.

For a research assistant over 600 ArXiv ML papers (many of which are recent), this is fatal. The entire value of the tool is access to *current* work.

The RAG Solution: Retrieve First, Then Generate

Retrieval-Augmented Generation (RAG) fixes both problems with a simple but powerful idea: **give the model the relevant documents at query time, inside the prompt.**

Think of it like the difference between two kinds of exams:

- **Closed-book exam:** the student relies entirely on memorised knowledge. An LLM answering from parameters alone is a closed-book exam.
- **Open-book exam:** the student can consult their notes during the exam. RAG gives the LLM its "notes" — the retrieved documents — before it answers.

The model cannot hallucinate facts from a document it can read directly. And the documents can be updated at any time without retraining the model.

The Core Loop

1. **Retrieve** — the user's question is converted to a search query. The retriever finds the most relevant chunks from the knowledge base (our 600 ArXiv papers).
2. **Prompt** — those chunks are inserted into a prompt template alongside the original question. The LLM now has the evidence it needs.
3. **Generate** — the LLM reads the evidence and writes an answer grounded in it.

Concrete example

User asks: "What are the key contributions of the paper on chain-of-thought prompting?"

Without RAG: The LLM might describe CoT correctly in broad strokes but invent specific results or misattribute the paper.

With RAG: The retriever finds the actual CoT paper's abstract in the index. The LLM reads the abstract in the prompt and summarises what it actually says.

RAG vs Fine-Tuning

A common question: if you want the model to know about new information, why not just fine-tune it on that information?

Concern	Fine-tuning	RAG
Adding new documents	Retrain (hours–days)	Reindex (minutes)
Knowledge provenance	Opaque (baked into weights)	Transparent (source chunks visible)
Hallucination risk	Still present	Reduced (evidence in-context)

Concern	Fine-tuning	RAG
Cost	High (GPU compute)	Low (embedding + vector search)
Best for	Teaching <i>style and behaviour</i>	Teaching <i>factual knowledge</i>

Rule of thumb

Fine-tune when you want the model to behave differently. Use RAG when you want the model to know different things.

They are not mutually exclusive — you can fine-tune a model to follow a specific answer format and then deploy it with RAG to supply current knowledge.

Three Levels of RAG

This tutorial is structured around three progressively more capable RAG architectures. Think of them as a staircase.

Naive RAG is the baseline: embed the query, find the top-5 chunks, paste them into a prompt, call the LLM. Simple, fast, and surprisingly effective. We build this in Part 1.

Advanced RAG layers on improvements: better retrieval (hybrid dense + BM25 search), a re-ranker to filter noise, and query rewriting to handle vague questions. Part 2 shows how each improvement moves the evaluation metrics.

Agentic RAG is where the LLM becomes a *reasoning agent*. Instead of a fixed retrieve → generate pipeline, the agent decides whether it needs to retrieve, what query to issue, whether the results are sufficient, and whether to loop again. This is the architecture that handles multi-hop questions and complex research tasks. Part 3.

Definition — Agentic AI

An *agent* is an LLM that can take actions in a loop: observe → think → act → observe. In agentic RAG, the LLM's "act" step includes issuing retrieval queries, and it loops until it has enough evidence to answer confidently.

What This Project Builds

Across all three notebooks you will build a complete RAG pipeline over 600 ArXiv ML/AI papers:

- Embeddings via **qwen3-embedding:0.6b** running locally through Ollama (1024 dimensions)
- A **FAISS** index for fast semantic search
- A **BM25** keyword index for exact-term matching
- Answer generation via **granite4.1:8b** (also local, also through Ollama)

By the end of Part 3, you will have a system that can answer research questions like "What methods have been proposed to improve reasoning in LLMs?" by retrieving and synthesising evidence from multiple papers — without a single API call to a paid service.

The next section explains the technology that makes semantic search possible: embeddings.

Embeddings — Text as Vectors

A search engine that can find *conceptually similar* documents — even when they share no words in common with the query — relies on a deceptively simple idea: turn every piece of text into a list of numbers, and define "similar meaning" as "similar numbers".

Those lists of numbers are called **embeddings**.

What Is an Embedding?

An embedding model is a neural network trained on massive amounts of text. Its job is to map any string of text to a fixed-size numerical vector.

```
"attention mechanism" → [0.12, -0.43, 0.87, 0.02, ..., -0.11] # 1024 numbers
"self-attention in LLMs" → [0.15, -0.39, 0.81, 0.07, ..., -0.08] # 1024 numbers
"deep learning for NLP" → [0.03, 0.71, -0.22, 0.59, ..., 0.44] # 1024 numbers
```

The first two sentences mean similar things, so the model places them close together in vector space. The third sentence is on a related but different topic, so its vector points in a somewhat different direction.

Definition — Embedding

An *embedding* is a dense, fixed-length vector representation of a piece of text. The numbers encode meaning: texts with similar meaning map to nearby vectors.

Think of it like a map. On a geographical map, Paris and Lyon are close together because they are both French cities. London is further away. Beijing is far across the map. An embedding space does the same thing for *meaning* instead of geography.

Intuition: Similar Meanings = Similar Directions

The most important property of embeddings is that **semantic similarity corresponds to geometric proximity**. But "proximity" in high dimensions is measured by *angle*, not distance. Two vectors that point in nearly the same direction have similar meaning.

In reality these vectors live in 1024 dimensions, not 2, so you cannot visualise them directly. But the angle intuition holds at any dimensionality.

Cosine Similarity: Measuring the Angle

The standard way to measure similarity between two embedding vectors is **cosine similarity**: it computes the cosine of the angle between them.

$$\text{cosine_similarity}(\mathbf{a}, \mathbf{b}) = \frac{\mathbf{a} \cdot \mathbf{b}}{\|\mathbf{a}\| \cdot \|\mathbf{b}\|}$$

Where:

- $\mathbf{a} \cdot \mathbf{b}$ is the dot product: $\sum_i a_i \cdot b_i$
- $\|\mathbf{a}\|$ is the Euclidean norm (magnitude): $\sqrt{\sum_i a_i^2}$

The result is always between -1 and 1:

Value	Meaning
1.0	Identical direction – very similar meaning
0.7	Close – related topics

Value	Meaning
0.0	Perpendicular — unrelated
-1.0	Opposite direction — antonyms / contradictions

Worked example (3 dimensions for clarity)

```
import numpy as np

a = np.array([0.6, 0.8, 0.0]) # "attention mechanism"
b = np.array([0.5, 0.7, 0.1]) # "self-attention in transformers"
c = np.array([-0.3, 0.1, 0.9]) # "gradient descent"

def cosine_sim(x, y):
    return np.dot(x, y) / (np.linalg.norm(x) * np.linalg.norm(y))

print(cosine_sim(a, b)) # 0.997 ← very similar
print(cosine_sim(a, c)) # 0.065 ← unrelated
```

L2 Normalisation: The Shortcut That Matters

Computing cosine similarity requires dividing by both magnitudes — two extra operations per comparison. When you are searching across 600 papers (tens of thousands of chunks), this adds up.

There is a cleaner approach: **L2-normalise every vector before storing it.**

L2 normalisation means dividing a vector by its own magnitude so the result has magnitude exactly 1.0 (a "unit vector"):

$$\hat{\mathbf{v}} = \frac{\mathbf{v}}{\|\mathbf{v}\|}$$

After normalisation, the magnitude terms in the cosine formula both equal 1, so:

$$\text{cosine_similarity}(\hat{\mathbf{a}}, \hat{\mathbf{b}}) = \hat{\mathbf{a}} \cdot \hat{\mathbf{b}}$$

The dot product between two unit vectors is the cosine similarity. No division required at search time. This is exactly why we use `FAISS IndexFlatIP` (inner product) rather than `IndexFlatL2` — the inner product over L2-normalised vectors gives us cosine similarity for free.

Here is the exact normalisation code from `src/ingest.py`:

```
# src/ingest.py - embed_texts()
embeddings = np.array(all_embeddings, dtype=np.float32)

# L2-normalise: divide each vector by its own Euclidean magnitude.
norms = np.linalg.norm(embeddings, axis=1, keepdims=True)
embeddings = embeddings / np.maximum(norms, 1e-10)
```

The `np.maximum(..., 1e-10)` guard prevents division by zero if a zero vector ever slips through (degenerate case, but worth handling).

Embedding Dimensions: The Quality–Speed Tradeoff

Our project defines two embedding models:

```
# src/ingest.py
EMBED_MODEL_PRIMARY = "qwen3-embedding:4b" # 4096-dim - high quality
EMBED_MODEL_LITE     = "qwen3-embedding:0.6b" # 1024-dim - fast
```

Property	qwen3-embedding:0.6b	qwen3-embedding:4b
Dimensions	1024	4096
Model parameters	~0.6 billion	~4 billion
FAISS index size (600 docs)	~10 MB	~40 MB
Embedding speed	~60 s for 500 docs	~5 min for 500 docs
Retrieval quality	Good	Excellent
RAM required	~1 GB	~5 GB

More dimensions means a richer representational space — the model can encode more nuanced distinctions. But it also means more memory, slower embedding, and slower search. For a tutorial corpus of 600 papers, 1024 dimensions is the right default. Swap to the 4b model when you want maximum quality on a production corpus.

Matching models at query time

You **must** embed queries with the same model used to build the index. Mixing `0.6b` for indexing and `4b` for queries produces vectors from different geometric spaces — the dot products become meaningless. `src/ingest.py` enforces this by accepting the model name as a parameter that flows through the whole pipeline.

How Ollama Serves Embeddings Locally

Ollama runs LLMs and embedding models as local HTTP servers. The `ollama` Python client wraps the REST API with a clean interface:

```
import ollama

response = ollama.embed(model="qwen3-embedding:0.6b", input=["your text here"])
# response["embeddings"] is a list of lists: [[float, float, ...]]
```

Ollama keeps the model loaded in GPU/CPU memory between calls, so repeated calls are fast. The first call after a system restart includes a model load (~2–5 seconds).

The `embed_query()` Function

At retrieval time, each user question is embedded with a single call. The function is deliberately separated from `embed_texts()` (the bulk embedder) because queries are always embedded one at a time and need a specific output shape for FAISS:

```
# src/ingest.py
def embed_query(query: str, model: str = EMBED_MODEL_LITE) -> np.ndarray:
    """
    Embed a single query string and return a normalised 1D numpy vector.
    Returns float32 array of shape (1, embedding_dim), L2-normalised.
    """
    response = ollama.embed(model=model, input=[query])
    vec = np.array(response["embeddings"][0], dtype=np.float32)
    vec = vec / np.maximum(np.linalg.norm(vec), 1e-10)
    return vec.reshape(1, -1) # shape (1, 1024) - FAISS expects 2D input
```

The output shape `(1, 1024)` matches what `faiss_index.search()` expects. A subtle but important detail: FAISS always expects a 2D array even for a single query.

Why qwen3-embedding:0.6b?

The Qwen3 embedding series is Alibaba's open-weight embedding family, released in 2025. The 0.6b model was chosen for this project for three reasons:

1. **It runs on consumer hardware.** The 0.6b model fits comfortably within 1–2 GB RAM, making it accessible on any laptop with 8 GB+ RAM.
2. **Strong multilingual and technical vocabulary.** Qwen3 was trained on a corpus heavy with scientific and technical text, which means it understands ML/AI terminology well out of the box.
3. **The quality–speed tradeoff is favourable at this scale.** At 600 papers, the 4b model produces marginal quality gains over the 0.6b model that are not worth the 4x embedding time increase.

 Unverified benchmark caveat

The claim that 0.6b vs 4b shows marginal gains at 600 papers is based on qualitative testing during project development, not a formal BEIR or MTEB evaluation. Part 2 of this tutorial includes a retrieval evaluation framework — you can run a formal comparison yourself.

Summary

Concept	What it means in this project
Embedding	Each paper chunk → 1024 float32 numbers
Similarity metric	Cosine similarity via dot product
Normalisation	All vectors are L2-normalised before storage
Index type	FAISS IndexFlatIP (inner product = cosine for unit vectors)
Embedding model	qwen3-embedding:0.6b via Ollama

Now that you understand how text becomes numbers and how those numbers are compared, the next section explains where those numbers live: the vector database.

Vector Databases

You have an ArXiv corpus (current baseline 4,000 papers; legacy baseline 600), each converted to one or more embedding vectors of 1024 numbers. When a user asks a question, you embed the question and want to find the 5 vectors in that collection that are most similar to the question's vector. How do you store those vectors so that query is fast?

A regular database will not help you here.

Why Regular Databases Cannot Do This

SQL databases are excellent at exact lookups:

```
SELECT * FROM papers WHERE category = 'cs.AI' AND year = 2024;
```

They can also do range queries, joins, and aggregations. What they cannot do efficiently is: **"find me the 5 rows whose embedding column is closest in cosine similarity to this query vector."**

There is no SQL index structure designed for that question. You would have to load every row, compute cosine similarity against the query, and sort — a full table scan for every single query. At 4,000 papers that takes milliseconds. At 6 million papers it takes tens of seconds per query.

Definition — Nearest Neighbour Search

Given a query vector $\mathbf{q}$ and a collection of stored vectors $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n\}$, find the k vectors with the highest cosine similarity to $\mathbf{q}$. This problem is called *k-Nearest Neighbour (k-NN) search*.

Vector databases are purpose-built for k-NN search. They use specialised index structures — exact or approximate — that make this query fast even at millions of vectors.

FAISS — The Index We Use in This Project

FAISS (Facebook AI Similarity Search) is an open-source C++ library with Python bindings, developed by Meta's AI Research team. It is not a "database" in the traditional sense — there is no server process, no authentication, no SQL. It is a library: you build an index in-process, add vectors to it, and search it.

Think of FAISS as a very smart filing system. You hand it a stack of index cards (vectors), it sorts and organises them, and when you ask "which 5 cards are most similar to this new card?", it tells you instantly.

IndexFlatIP — Exact Brute-Force Search

The index type used in this project is `IndexFlatIP`:

- **Flat** means the index stores every vector verbatim — no compression, no approximation.
- **IP** means it scores vectors by Inner Product (dot product).
- Because our vectors are L2-normalised, inner product equals cosine similarity (see the [Embeddings](#) section).

```
# src/ingest.py - build_faiss_index()
import faiss

def build_faiss_index(embeddings: np.ndarray) -> faiss.IndexFlatIP:
    n, dim = embeddings.shape          # e.g. (1200, 1024)
    index = faiss.IndexFlatIP(dim)     # create a 1024-dim inner-product index
    index.add(embeddings)              # add all vectors at once
    return index
```

Searching is one line:

```
scores, indices = index.search(query_vec, k=5)
# scores: float32 array of shape (1, k) - cosine similarities
# indices: int64 array of shape (1, k) - position of each result in the corpus
```

Exact vs Approximate Search

`IndexFlatIP` performs **exact** search — it computes the dot product against every stored vector and returns the true top-k. This is always correct, but it is $O(n \cdot d)$ per query (n vectors, d dimensions).

Corpus size	IndexFlatIP query time	Verdict
10K vectors	< 1 ms	Fine
1M vectors	~500 ms	Borderline
100M vectors	~50 s	Unacceptable

For large corpora, FAISS provides approximate indices that trade a small accuracy loss for dramatic speed gains:

- **IndexIVFFlat** — divides the space into "cells"; searches only nearby cells.
- **IndexHNSW** — hierarchical graph structure; sub-millisecond queries at millions of vectors.
- **IndexPQ** — product quantisation; compresses vectors to reduce memory.

For this project's tutorial-scale corpora, `IndexFlatIP` is exactly right. The corpus fits in memory, queries take microseconds, and there is zero accuracy loss.

When to switch to approximate search

If your corpus grows beyond ~500K vectors and query latency exceeds 100 ms, switch to `IndexIVFFlat` (good first step) or `IndexHNSW` (best latency). FAISS makes this a one-line change — same API, different index class.

ChromaDB — Persistent, Filterable, Local or Server

ChromaDB is a purpose-built open-source vector database. Unlike FAISS, it is a full database: it persists to disk automatically, survives process restarts, stores metadata alongside vectors, and supports metadata filters at query time.

```
import chromadb

client = chromadb.PersistentClient(path="./chroma_db")
collection = client.get_or_create_collection("arxiv_papers")

# Upsert documents (ChromaDB embeds them or accepts pre-computed vectors)
collection.upsert(
    ids=["paper_001", "paper_002"],
    documents=["abstract text 1", "abstract text 2"],
    metadatas=[{"category": "cs.AI"}, {"category": "cs.LG"}],
)

# Semantic search with a metadata filter
results = collection.query(
    query_texts=["chain of thought reasoning"],
    n_results=5,
    where={"category": "cs.AI"}, # metadata filter
)
```

The metadata filter (`where`) is a feature FAISS does not have — with FAISS you retrieve by vector similarity alone and then filter the results in Python. ChromaDB pushes the filter into the index, which is more efficient when you only want results from a specific category, date range, or author.

ChromaDB also runs as a standalone server, making it accessible from multiple processes or services — a step toward a deployed application.

ChromaDB in this project

ChromaDB is introduced in **Part 4** of this tutorial (vector store swap-out). We cover it here so you understand the landscape before you need to choose.

Pinecone — Cloud-Native, Serverless, Production Scale

Pinecone is a managed cloud vector database. You do not install anything — you create an index via the Pinecone console or API, push vectors to it, and query it from anywhere over HTTP.

```
from pinecone import Pinecone

pc = Pinecone(api_key="your-api-key")
index = pc.Index("arxiv-papers")

# Upsert vectors
index.upsert(vectors=[
    {"id": "paper_001", "values": embedding_list, "metadata": {"category": "cs.AI"}},
])

# Query
results = index.query(vector=query_embedding, top_k=5, include_metadata=True)
```

Pinecone handles sharding, replication, and hardware scaling automatically. The "serverless" tier scales to zero when idle, making it cost-effective for low-traffic applications. The managed tier provides dedicated resources for consistent latency.

The tradeoff: Pinecone is a paid service (with a free tier), your vectors leave your machine, and you depend on their API availability.

Pinecone in this project

Pinecone integration is also covered in **Part 4**. The MCP Pinecone server (`mcp__pinecone`) is available in this environment for experimenting with the Pinecone API directly.

Comparison: FAISS vs ChromaDB vs Pinecone

Feature	FAISS	ChromaDB	Pinecone
Type	Library (in-process)	Embedded / Server DB	Managed cloud service
Persistence	Manual (save/load files)	Automatic	Automatic (cloud)
Metadata filters	No (post-filter in Python)	Yes	Yes
Setup complexity	Low	Low	Low (API key)

Feature	FAISS	ChromaDB	Pinecone
Data leaves machine	No	No	Yes
Cost	Free	Free	Free tier / paid
Max scale	~10M vectors (exact)	~1M vectors (local)	Billions (managed)
Best for	Research, prototypes, offline	Apps needing persistence and filtering	Production, multi-region, large scale
Used in this project	Parts 1–3	Part 4	Part 4

How FAISS Is Used in This Project

The full lifecycle of the FAISS index spans two phases:

Build time (notebook `01_naive_rag.ipynb`, run once):

Query time (core retrieval notebooks):

The `save_index_and_chunks()` and `load_index_and_chunks()` functions in `src/ingest.py` handle the persistence. The index and the chunk metadata list are always saved together — the integer positions FAISS returns are only meaningful if you have the matching `artifacts/faiss_index/chunks.pkl` to look up.

Summary

System	Role in this project
FAISS IndexFlatIP	Exact cosine similarity search over L2-normalised vectors
ChromaDB	Persistent alternative with metadata filtering (Part 4)
Pinecone	Cloud-native alternative for production scale (Part 4)

Now that you know how vectors are stored and searched, the next section covers the other half of the retrieval story: keyword-based search with BM25.

BM25 and Sparse Retrieval

Semantic search with embeddings is powerful, but it has a specific and predictable failure mode. Understanding it explains why BM25 exists as a complement to vector search — and why the two together outperform either alone.

The Limits of Semantic Search

Consider these two queries:

1. "How do transformer models handle long sequences?"
2. "What does the Mamba SSM paper claim about RWKV?"

Query 1 is a conceptual question. Even if the relevant papers use different words — "long-context window", "extended attention span", "sequence length scaling" — an embedding model can find them, because all those phrases map to nearby regions of vector space.

Query 2 is an exact-term question. The words "Mamba", "SSM", and "RWKV" are proper nouns — specific model names. They appeared rarely or never in the embedding model's training data. The model cannot reliably distinguish "Mamba SSM" from any other sequence model just by the *meaning* of the name; the name itself is the signal.

This is where semantic search loses to classical keyword search:

- **Model names:** Mamba, RWKV, LLaMA, Mistral, Qwen
- **Dataset names:** SQuAD, MMLU, HumanEval, BEIR
- **Acronyms:** RAG, LoRA, QLoRA, PEFT, RLHF
- **Paper IDs:** arXiv:2305.10403
- **Rare technical terms** that the embedding model has never seen in context

For all of these, a retriever that matches exact tokens beats one that reasons about meaning.

The core insight

Embeddings encode *generalised meaning*. Keyword search encodes *exact tokens*. They are complementary, not competing. This is why Part 2 of this tutorial introduces hybrid retrieval: dense + sparse together.

What Is Sparse Retrieval?

A "sparse" representation of a document is a vector indexed by vocabulary. Most entries are zero (the word does not appear); a few are non-zero (the word does appear).

Imagine a vocabulary of 100,000 English words. A 200-word paper abstract might contain 150 unique words — so its sparse vector has 99,850 zeros and 150 non-zero values. Compare this to a dense embedding: 1024 non-zero values for every document, regardless of content.

Property	Dense (embedding)	Sparse (BM25 / TF-IDF)
Vector size	Fixed (e.g. 1024)	Vocabulary size (~100K+)
Non-zero entries	All 1024	A few hundred per doc
Captures	Semantic meaning	Exact token overlap
Handles new vocab	Poorly (OOV)	Well (new term = new dimension)
Main algorithm	Cosine similarity	BM25

The BM25 Formula, Explained Step by Step

BM25 (Best Match 25) was published in 1994 and has remained the standard for keyword search for thirty years. Here is the scoring formula:

For a query Q with terms $q_1, q_2, \dots, q_n$ and a document D :

$$\text{score}(D, Q) = \sum_{i=1}^n \text{IDF}(q_i) \cdot \frac{f(q_i, D) \cdot (k_1 + 1)}{f(q_i, D) + k_1 \cdot \left(1 - b + b \cdot \frac{|D|}{\text{avgdl}}\right)}$$

That looks intimidating. Let's unpack each piece.

Term Frequency: $f(q, D)$

$f(q, D)$ is simply the count of how many times the query term q appears in document D .

A document that uses the word "attention" 10 times is probably more about attention than one that uses it once. Term frequency captures this.

Inverse Document Frequency: $\text{IDF}(q)$

$$\text{IDF}(q) = \log\left(\frac{N - \text{df}(q) + 0.5}{\text{df}(q) + 0.5}\right)$$

Where N is the total number of documents and $df(q)$ is the number of documents that contain term q .

IDF penalises terms that appear in many documents. The word "the" appears in every document — its IDF is nearly zero, so it contributes almost nothing to the score. The term "Mamba" appears in very few documents — its IDF is high, so a match on it strongly boosts the score.

This is the "rare terms matter more" principle.

Saturation: the k_1 term

Notice the numerator and denominator both contain $f(q, D)$. When $f(q, D)$ is small, the fraction grows quickly. But as $f(q, D)$ gets very large, the fraction approaches $(k_1 + 1)$ — it saturates.

Why saturation matters

If document A mentions "attention" 5 times and document B mentions it 50 times, document B is not 10x more relevant. After a point, more occurrences stop adding information. BM25 models this saturation explicitly. Plain TF-IDF does not — which is one of the reasons BM25 outperforms TF-IDF.

The default value $k_1 = 1.5$ means scores saturate at around 3–5 term occurrences.

Length Normalisation: the b term

$$1 - b + b \cdot \frac{|D|}{\text{avgdl}}$$

$|D|$ is the length of the document; avgdl is the average document length across the corpus. The parameter $b = 0.75$ controls how strongly length is penalised.

A long document has a higher chance of containing a query term just by chance. Length normalisation corrects for this: a term that appears once in a short abstract is treated as more significant than the same term appearing once in a 10-page paper.

BM25 vs TF-IDF: the short version

TF-IDF: score = TF × IDF. Simple product, no saturation, no length normalisation. BM25: adds saturation (k_1) and length normalisation (b). These two additions are why BM25 consistently outperforms TF-IDF on benchmark retrieval tasks.

How BM25 Is Built in This Project

BM25Retriever in `src/retriever.py` wraps the `rank_bm25` library:

```
# src/retriever.py
from rank_bm25 import BM25Okapi

class BM25Retriever:
    def __init__(self, chunks: list[dict]) -> None:
        tokenised_corpus = [_tokenise(chunk["text"]) for chunk in chunks]
        self.bm25 = BM25Okapi(tokenised_corpus)

    def retrieve(self, query: str, k: int = 5) -> list[dict]:
        query_tokens = _tokenise(query)
        scores = self.bm25.get_scores(query_tokens)
        top_k_indices = np.argsort(scores)[::-1][:k]
        ...
```

`BM25Okapi` is the most common variant of BM25 (the "Okapi" refers to the Okapi system at City University London where the formula was developed). It uses $k_1 = 1.5$ and $b = 0.75$ as defaults — well-validated parameters across many document retrieval benchmarks.

Our Tokenisation Improvement

Tokenisation determines what "terms" BM25 scores on. The choice matters more than most tutorials acknowledge.

The Old Approach (whitespace split only)

```
# OLD - naive whitespace split
tokens = text.lower().split()
```

Problems with this approach:

- `"Transformer."` and `"Transformer"` are different tokens (trailing punctuation).
- `"the"`, `"is"`, `"of"` consume IDF budget — they appear in nearly every document, their IDF is close to zero, but the model still processes them on every query.
- `"a"` and `"A"` would be different tokens if `.lower()` is missed anywhere.

The New Approach (lowercase + punctuation strip + stop words)

```
# src/retriever.py - _tokenise()

BM25_STOP_WORDS: frozenset[str] = frozenset({
    "the", "a", "an", "is", "are", "was", "were", "be", "been", "being",
    "have", "has", "had", "do", "does", "did", "will", "would", "could",
    "should", "may", "might", "shall", "can", "of", "in", "on", "at",
    "to", "for", "with", "by", "from", "as", "this", "that", "these",
    "those", "it", "its", "we", "our", "they", "their", "which", "who",
    "and", "or", "but", "not", "no", "nor", "so", "yet", "both", "each",
    "about", "than", "more", "also", "such", "into", "its", "over",
})

def _tokenise(text: str) -> list[str]:
    """Lowercase, strip non-alphanumeric chars, remove stop words and single-char tokens."""
    tokens = re.sub(r"[^a-z0-9]", " ", text.lower()).split()
    return [t for t in tokens if t not in BM25_STOP_WORDS and len(t) > 1]
```

What each step does:

1. `.lower()` — case-fold everything so "Transformer" and "transformer" are the same token.
2. `re.sub(r"[^a-z0-9]", " ", ...)` — replace every non-alphanumeric character with a space. Punctuation, hyphens, colons all become word boundaries. "chain-of-thought" becomes three tokens: ["chain", "thought"] (after stop word removal).
3. Stop word filter — removes ~50 common function words that carry no semantic signal for BM25. This frees up the IDF budget for terms that actually matter.
4. Single-character filter (`len(t) > 1`) — drops leftover single characters from punctuation splitting.

Before and after tokenisation

Input: "The attention mechanism in transformer-based LLMs."

Old (whitespace split): ["the", "attention", "mechanism", "in", "transformer-based", "llms."]

New (improved): ["attention", "mechanism", "transformer", "based", "llms"]

The improved version removes stop words ("the", "in"), strips punctuation from "llms.", and splits the hyphenated compound — giving BM25 cleaner, denser signal to work with.

The same `_tokenise()` function is applied to **both** the corpus at index-build time and the query at search time. This symmetry is mandatory: BM25 scores are only meaningful when the corpus tokens and the query tokens come from the same vocabulary.

When BM25 Wins and When It Loses

BM25 wins when:

- The query contains specific technical terms, proper nouns, or acronyms that are unlikely to have rich semantic representations in the embedding space.
- The relevant document uses the exact same terminology as the query — no paraphrasing involved.
- The answer is "find me everything about LoRA" rather than "find me things conceptually similar to parameter-efficient fine-tuning".

BM25 loses when:

- The query and the relevant document use completely different vocabulary. ("How do LLMs generate text?" vs a paper discussing "autoregressive decoding" — zero keyword overlap, but highly relevant.)
- The query is long and conversational — many tokens, most of which are stop words that BM25 will discard.
- The relevant documents are short — length normalisation compresses scores and ranking becomes noisy at very short chunk lengths.

This complementary failure-mode profile is exactly why hybrid retrieval (combining dense and BM25) is the subject of Part 2. BM25 catches what embeddings miss; embeddings catch what BM25 misses.

Summary

Concept	Detail
BM25 variant	BM25Okapi ($k_1 = 1.5$, $b = 0.75$)
Library	<code>rank_bm25</code>
Tokenisation	lowercase + punct strip + stop word removal
Index built over	All chunk texts (~1,200 chunks)
Scores	Raw BM25 values (not normalised to 0–1)
Best for	Exact-term queries, proper nouns, acronyms
Worst for	Paraphrase and conceptual queries

The next part of this tutorial builds the complete Naive RAG pipeline, combining everything you have learned here: embed the corpus, index it in FAISS, and generate answers with Granite 4.1 — end to end, fully local.

Hybrid Search

Single retrievers have blind spots. This chapter explains why, and how combining two complementary strategies — dense embeddings and keyword matching — covers most of them.

The Problem with Going Solo

Imagine you ask: *"What does the attention mechanism do in transformers?"*

A **dense retriever** (embedding-based) handles this beautifully. It does not look for the exact word "attention" — it understands the semantic neighbourhood of "attention mechanism" and retrieves chunks that discuss concepts like "query-key-value", "softmax weighting", and "self-attention", even if those chunks never use the phrase you typed.

Now imagine you ask: *"Does GPT-4o-mini support structured outputs?"*

The dense retriever struggles here. "GPT-4o-mini" is a specific product identifier. Embedding models collapse rare tokens into fuzzy semantic regions — "GPT-4o-mini" and "GPT-4o" are likely to land in nearly the same embedding neighbourhood, and chunks about the right model may not rank first.

A **BM25 keyword retriever** shines here. It counts exact term occurrences. If a chunk contains "GPT-4o-mini" three times, it gets a high score for that query regardless of semantic similarity.

The observation is simple: **the two retrievers fail on complementary queries**. Combining them is consistently better than either alone. This is hybrid search.

Definition — Hybrid Retrieval

Hybrid retrieval runs two or more retrieval strategies independently, then **fuses** their result lists into a single ranked output. The fusion step is where the design decisions live.

Two Ways to Fuse

Once you have two ranked lists, you need to merge them. Two approaches are common.

Alpha-Weighted Score Fusion

The intuitive approach: treat both scores as numbers and average them, with a weight `alpha` controlling how much you trust each retriever.

The catch is that **scores live on different scales**. A BM25 score of 14.3 and a cosine similarity of 0.87 are not comparable. A document that scores 14.3 in BM25 and 0.87 in dense search is not automatically the best — you cannot add apples and oranges.

The fix is **min-max normalisation**: squeeze each retriever's score range to [0, 1] before blending.

```
dense_norm = (dense_score - dense_min) / (dense_max - dense_min)
bm25_norm = (bm25_score - bm25_min) / (bm25_max - bm25_min)

hybrid_score = alpha * dense_norm + (1 - alpha) * bm25_norm
```

With `alpha=0.7` (this project's default), the blend is 70% semantic, 30% keyword.

src/retriever.py — HybridRetriever._alpha_fusion()

```
def _alpha_fusion(self, dense_results, bm25_results, k):
    """Min-max normalise both score sets, then blend with alpha."""
    dense_map = {r["chunk_id"]: r["score"] for r in dense_results}
    bm25_map = {r["chunk_id"]: r["score"] for r in bm25_results}

    all_ids = set(dense_map) | set(bm25_map)

    d_vals = list(dense_map.values())
    d_min, d_max = (min(d_vals), max(d_vals)) if d_vals else (0, 1)

    b_vals = list(bm25_map.values())
    b_min, b_max = (min(b_vals), max(b_vals)) if b_vals else (0, 1)

    def norm_dense(s):
        return (s - d_min) / max(d_max - d_min, 1e-10)

    def norm_bm25(s):
        return (s - b_min) / max(b_max - b_min, 1e-10)

    fused = []
    for cid in all_ids:
        chunk = dict(all_chunks[cid])
        d_score = norm_dense(dense_map.get(cid, d_min))
        b_score = norm_bm25(bm25_map.get(cid, b_min))
        chunk["score"] = self.alpha * d_score + (1 - self.alpha) * b_score
        chunk["retriever"] = "hybrid"
        fused.append((chunk["score"], chunk))

    fused.sort(key=lambda x: x[0], reverse=True)
    return [c for _, c in fused[:k]]
```

Score normalisation is query-dependent

The min and max are computed from *this query's* result set, not the corpus. A document that appears only in the dense results gets a BM25 score of `bm25_min` (which normalises to 0.0). This is intentional — a document the keyword retriever has never heard of should not get a free BM25 bonus.

Reciprocal Rank Fusion (RRF)

Score fusion has a subtle problem: it is sensitive to the *distribution* of scores, which changes with every query. On one query, dense scores might be tightly clustered between 0.80 and 0.95; on another, they might span 0.10 to 0.90. Normalising fixes the scale but not this distributional instability.

RRF sidesteps the problem entirely: **throw away the scores and only keep the ranks**.

The formula for a document d appearing across n retriever lists is:

$$\text{RRF}(d) = \sum_{i=1}^n \frac{1}{k + \text{rank}_i(d)}$$

where $k=60$ is a smoothing constant (60 is a widely-used empirical default) and $\text{rank}_i(d)$ is the position of document d in retriever i 's list (1-indexed).

Why $k=60$?

The constant k prevents rank-1 documents from dominating too strongly. Without it, $1/\text{rank}$ at rank 1 equals 1.0 — ten times more than rank 10's 0.1. With $k=60$, rank 1 gives $1/61 \approx 0.0164$ and rank 10 gives $1/70 \approx 0.0143$. The difference is still there, but it is gentler.

Worked Example

Suppose both retrievers return the same three documents but in different orders:

Document	Dense rank	BM25 rank
Doc A	1	3
Doc B	2	1
Doc C	3	2

RRF scores (with $k=60$):

Document	Dense contribution	BM25 contribution	Total RRF score
Doc A	$1/(60+1) = 0.01639$	$1/(60+3) = 0.01587$	0.03226
Doc B	$1/(60+2) = 0.01613$	$1/(60+1) = 0.01639$	0.03252

Document	Dense contribution	BM25 contribution	Total RRF score
Doc C	$1/(60+3) = 0.01587$	$1/(60+2) = 0.01613$	0.03200

Doc B wins because it was ranked first by at least one retriever and ranked consistently well by both. Doc A fell to last despite being ranked first by dense search, because BM25 ranked it poorly.

src/retriever.py – HybridRetriever._rrf_fusion()

```
def _rrf_fusion(self, dense_results, bm25_results, k):
    """Reciprocal Rank Fusion – rank-based, ignores raw scores."""
    scores: dict[str, float] = {}
    all_chunks: dict[str, dict] = {}

    for results in [dense_results, bm25_results]:
        for rank, chunk in enumerate(results):
            cid = chunk["chunk_id"]
            scores[cid] = scores.get(cid, 0.0) + 1.0 / (self.rrf_k + rank + 1)
            all_chunks[cid] = chunk

    ranked = sorted(scores.items(), key=lambda x: x[1], reverse=True)[:k]
    result = []
    for cid, score in ranked:
        chunk = dict(all_chunks[cid])
        chunk["score"] = score
        chunk["retriever"] = "hybrid-rrf"
        result.append(chunk)
    return result
```

Alpha vs RRF — When Does Each Win?

Situation	Prefer alpha fusion	Prefer RRF
Score distributions are stable	Yes	Either
Score distributions vary wildly query-to-query	No	Yes
You want to tune the dense/keyword balance	Yes (adjust <code>alpha</code>)	No (treats both equally)
You care about simplicity	Either	Yes (no tuning needed)
Your retrievers use incomparable score ranges	Requires care	Yes

What we found in this project

On our 20-query, 600-paper evaluation set, **alpha fusion (MRR 0.363) marginally outperformed RRF** when both were followed by cross-encoder reranking. The gap was small enough that RRF is a reasonable default — it requires no hyperparameter tuning and is robust out of the box. Alpha fusion wins here likely because `alpha=0.7` correctly weights the relatively stronger dense retriever on ML/AI research queries.

The Full Retrieval Pipeline

With hybrid search in place, the retrieval stage looks like this:

The next section covers the cross-encoder reranker — the step that converts a good top-10 into a precise top-5.

Reranking

Hybrid search gives you a good shortlist. A cross-encoder reranker turns that shortlist into a precise, ordered set. This chapter explains why a second retrieval stage is needed and how it works.

The Bi-Encoder Limitation

Every retriever we have built so far — dense, BM25, hybrid — shares a structural constraint: **query and document are evaluated independently**.

A bi-encoder (the embedding model behind dense search) works like this:

```
query    → encoder → q_vec ┌
                                     │ cosine_similarity → score
document → encoder → d_vec └
```

Each text is embedded separately. The score is computed as a single number from two vectors. The encoder that processes the query has never "seen" the document, and vice versa. There is no opportunity for the model to notice that a specific phrase in the query exactly matches a specific phrase in the document, or that the document uses a synonym the query relies on.

This is not a design flaw — it is a deliberate trade-off. Because embeddings are pre-computed for every document in the corpus, searching a million documents takes milliseconds (one dot-product per document, done in batch by FAISS). The bi-encoder is fast *because* it is independent.

But independence has a cost: **the model misses fine-grained query-document interactions**.

The Cross-Encoder: Joint Encoding

A cross-encoder processes query and document *together* in a single forward pass:

```
[query] [SEP] [document] → encoder → full attention → relevance score
```

Every token in the query can attend to every token in the document. The model can detect:

- Exact phrase matches ("chain-of-thought" in both query and doc)
- Paraphrase at the token level ("accuracy" in query, "performance" in doc)
- Negations and qualifiers ("does not improve" is different from "improves")
- Positional importance (the abstract's first sentence matters more than a footnote)

The result is a much more accurate relevance score — but at a price.

The Cost: Why You Cannot Use a Cross-Encoder Directly

Cross-encoding is $O(n)$ per query: you must run one forward pass for every candidate document. On a corpus of 600 papers split into roughly 6,000 chunks, that means 6,000 model forward passes per user query. A single forward pass takes ~20ms on CPU. The math is brutal:

$$6,000 \text{ chunks} \times 20\text{ms} = 120 \text{ seconds per query}$$

That is two minutes of latency for every question. A bi-encoder over the same corpus takes under a second.

The standard solution is **two-stage retrieval**:

Stage 1 is cheap enough to run over the full corpus. Stage 2 runs on 20 candidates — 20 forward passes instead of 6,000.

Stage 1 quality matters

The cross-encoder can only pick winners from what Stage 1 gave it. If the right document was not in the top-20, no amount of reranking can surface it. This is why we fetch 20 candidates (2× the final output size) in Stage 1, giving Stage 2 room to work.

The MS-MARCO Model

This project uses `cross-encoder/ms-marco-MiniLM-L-6-v2`.

- **MS-MARCO**: Microsoft Machine Reading Comprehension, a dataset of ~530,000 real Bing search queries paired with relevant passages. The model was trained to distinguish relevant from irrelevant passages for those queries.
- **MiniLM-L-6-v2**: a distilled, 6-layer transformer — fast enough for CPU inference. The model weights are 22 MB on disk.
- **Zero-shot on ArXiv**: MS-MARCO queries are general web searches, not academic research queries. The model was never trained on "what does attention do in a transformer" style questions — yet it generalises well, because the relevance signal (does this passage answer this question?) transfers across domains.

What the score means

The cross-encoder outputs a raw logit — an unbounded float. A higher logit means "more relevant." The absolute value has no meaning; only the relative ordering matters for reranking. You should not interpret a score of 8.2 as "82% relevant."

The Code

src/retriever.py — Reranker.rerank()

```
class Reranker:
    def __init__(
        self,
        model_name: str = "cross-encoder/ms-marco-MiniLM-L-6-v2",
    ) -> None:
        self.model = CrossEncoder(model_name)

    def rerank(
        self,
        query: str,
        candidates: list[dict],
        top_k: int = 5,
    ) -> list[dict]:
        if not candidates:
            return []

        # Build (query, passage) pairs for the cross-encoder
        pairs = [(query, c["text"]) for c in candidates]
        scores = self.model.predict(pairs) # one forward pass per pair

        # Zip scores back to chunks and sort descending
        scored = sorted(
            zip(scores, candidates),
            key=lambda x: x[0],
            reverse=True,
        )

        results = []
        for score, chunk in scored[:top_k]:
            chunk = dict(chunk)
            chunk["score"] = float(score)
            chunk["retriever"] = "reranked"
            results.append(chunk)

        return results
```

Key design choices:

1. **Batch prediction:** `self.model.predict(pairs)` sends all 20 pairs in one call. The `CrossEncoder` handles batching internally — this is more efficient than calling `predict` 20 times in a loop.

2. **Score overwrite:** The `"score"` key is replaced with the cross-encoder logit, discarding the hybrid fusion score. The cross-encoder's ordering is the one we trust.
3. **Retriever tag:** `"retriever": "reranked"` lets downstream code (and the evaluator) know which stage produced the final results.

Real Impact

On our evaluation set (20 queries, 600-paper corpus):

Retriever	MRR
Dense only	0.299
BM25 only	0.441
Hybrid (alpha)	0.330
Hybrid + Rerank	0.363

Reranking added **+0.033 MRR** over hybrid alone — a meaningful improvement that reflects the cross-encoder finding better orderings within each candidate set.

Why did BM25 alone beat hybrid in this eval?

Our 20-query evaluation set uses multi-keyword OR matching to define ground truth (a paper is relevant if it contains at least one query keyword). This definition naturally rewards keyword-based retrieval. BM25's strong showing here is partly a measurement artefact; on semantic or paraphrase queries, dense and hybrid methods tend to outperform BM25 on human-judged relevance.

The next section covers how we measure these numbers systematically — the evaluation metrics that power every result table in this tutorial.

Evaluation Metrics

Building a better retriever only matters if you can measure whether it is actually better. This chapter covers the metrics we use, what they mean, and an honest look at how our numbers changed when we moved from a 5-query to a 20-query evaluation set.

Why Evaluate? Two Failure Modes

A RAG system can fail in two independent ways:

Retrieval failure: The right documents are not in the top-k results. No matter how intelligent the LLM is, it cannot cite evidence it was never given. The answer will either be vague or fabricated.

Generation failure: The right documents were retrieved — they appear in the prompt context — but the LLM ignored them and produced an answer from its training weights instead. This is hallucination despite correct retrieval.

Evaluating only the final answer conflates both failure modes. You cannot tell whether a bad answer came from bad retrieval or a bad LLM. We evaluate each stage separately: retrieval metrics tell us if the right documents were found; generation metrics tell us if the LLM used them faithfully.

Retrieval Metrics

Setting Up the Problem

Before computing any metric, we need a ground truth. For each query in the evaluation set, we have a list of `relevant_ids` — paper IDs that we consider correct answers to that query. The retriever returns a ranked list of chunks. We project those chunks back to paper IDs and ask: *how well does the ranked list match the ground truth?*

Recall@k

Definition — Recall@k

Recall@k measures what fraction of the relevant documents appear anywhere in the top-k retrieved results.

$$\text{Recall@k} = \frac{|\text{relevant} \cap \text{top-k}|}{|\text{relevant}|}$$

Worked example: Suppose the ground truth says papers `[A, B, C]` are relevant. Your retriever's top-5 results are `[B, D, E, A, F]`.

- Relevant documents found in top-5: {A, B} → 2 out of 3
- Recall@5 = $\frac{2}{3} \approx 0.667$

Document C was not retrieved — one third of the relevant set was missed.

Recall@k answers: *did we find everything we needed?* It does not care about rank order; a document at position 5 counts the same as one at position 1.

Precision@k

Definition — Precision@k

Precision@k measures what fraction of the top-k results are actually relevant.

$$\text{Precision@k} = \frac{|\text{relevant} \cap \text{top-k}|}{k}$$

Using the same example: top-5 = [B, D, E, A, F], relevant = {A, B, C}.

- Relevant documents in top-5: {A, B} → 2 out of 5
- Precision@5 = $\frac{2}{5} = 0.400$

Three of the five returned documents (D, E, F) were noise.

Precision@k answers: *how much noise did we include?* This matters when the LLM prompt context is limited — every noise chunk displaces a potentially relevant one.

The recall-precision tradeoff

Increasing k improves recall (more chances to find relevant docs) but reduces precision (more noise in the results). In RAG we typically care more about precision because the LLM's context window is the bottleneck. Retrieving 100 chunks and hoping the LLM ignores the 95 noise ones is not a good strategy.

Mean Reciprocal Rank (MRR)

Definition — MRR

MRR is the average, across all queries, of the reciprocal of the rank at which the first relevant document appears.

$$\text{MRR} = \frac{1}{|Q|} \sum_{q \in Q} \frac{1}{\text{rank}_q^{\text{first relevant}}}$$

First relevant document at rank	Reciprocal rank
1	1.000 (perfect)
2	0.500
3	0.333
5	0.200
Not found	0.000

MRR is the most important metric for RAG. Here is why: when we pass retrieved chunks to the LLM, we typically pass the top-3 or top-5. If the single best document for a query is buried at rank 8, the LLM never sees it.

Recall@5 would tell you that document was "close" — it just missed the cut. MRR would tell you the retriever failed on that query (rank 8 means MRR contribution of $\frac{1}{8} = 0.125$, compared to a perfect 1.0 if it were ranked first).

MRR is therefore the primary metric we optimise in this project.

Generation Metrics

Faithfulness (LLM-as-Judge)

Faithfulness answers: *is the generated answer supported by the retrieved context?*

We ask a second LLM (we use `granite4.1:8b` as both generator and judge) to evaluate each answer. The judge is given the retrieved passages and the generated answer, and must determine whether every claim in the answer can be traced back to the passages.

`src/evaluator.py — score_faithfulness()`

```
prompt = """You are a strict factual evaluator. Read the context passages and the answer.
Determine if the answer is FULLY supported by the context — no claims go beyond
what the context states.
```

```
Context:
{context_text}
```

```
Answer: {answer}
```

```
Respond with JSON only: {"faithful": true or false, "reason": "one sentence"}"""
```

The function returns `1.0` for faithful, `0.0` for not. In this repository, faithfulness is reported per experiment artifact (for example `artifacts/eval_results/03_agentic_rag_4000.json` and `artifacts/rag_v2/*/*_metrics.json`) and should be interpreted in the context of the specific query set and runtime mode used for that run.

Limitations of LLM-as-judge

LLM judges can be inconsistent: the same (answer, context) pair may get different scores on different runs. They can also be sycophantic — rating confidently-written answers as faithful even when the underlying claim is not in the context. Treat faithfulness scores as directional signals, not exact measurements. For rigorous evaluation, human annotation on a sample is the gold standard.

The Eval Set Problem: 5 Queries vs 20 Queries

Early in this project, we evaluated with only **5 queries**. The numbers looked encouraging:

Metric	5-query eval
Dense MRR	0.600
BM25 MRR	0.800
Hybrid+Rerank MRR	0.800

These numbers are almost certainly inflated. With 5 queries, each query has a 20% impact on the average. A single lucky query — one where the relevant paper happened to land at rank 1 — can swing MRR by 0.2. The variance is enormous and the numbers are not reliable.

We expanded the evaluation set to **20 queries** and the picture changed:

Retriever	5-query MRR	20-query MRR
Dense	0.600	0.299
BM25	0.800	0.441
Hybrid	—	0.330
Hybrid+Rerank	0.800	0.363

Every metric dropped — not because the system got worse, but because the evaluation set got more honest. Twenty queries still is not a large evaluation set by research standards (papers typically report on hundreds to thousands of queries), but it is substantially more representative than five.

Lesson: small eval sets lie

If your evaluation set is small enough that one query can move your headline metric by 10–20%, your numbers are not trustworthy. Before celebrating an improvement, check how many queries are behind the number. The correct reaction to a 0.2 MRR improvement on a 5-query eval set is curiosity, not celebration.

The Ground Truth Definition

Our ground truth uses **multi-keyword OR matching**: a paper is considered relevant to a query if its title or abstract contains at least one of the query's keywords.

This is a practical, automated approach — it scales to 600 papers without human annotation. But it has limitations:

- A paper can be highly relevant without containing any query keyword (paraphrase problem)
- A paper can contain the keyword without being truly relevant (polysemy problem)
- The definition rewards keyword-based retrieval (which is why BM25 scores well)

This is the honest tradeoff. We note in the results where this measurement choice affects the interpretation.

Putting It Together

The metrics cascade from retrieval to generation:

Good MRR means the right evidence reached the LLM. Good faithfulness means the LLM used that evidence rather than hallucinating. Only when both are high is the system actually working.

The next section covers how the system decides *what to do* when retrieval quality is low — the agentic loop that makes Part 3 different from Parts 1 and 2.

Agentic AI and LangGraph

Parts 1 and 2 of this tutorial build *pipelines*: a fixed sequence of steps that runs the same way every time. Part 3 builds something different — an *agent* that decides what to do next based on what it has seen so far. This chapter explains the key concepts before you write a single line of agentic code.

What Makes Something "Agentic"?

The word "agentic" is overused in AI marketing. Here is a precise definition that covers what we actually build:

Definition — Agentic AI

A system is *agentic* when the **output of an LLM call determines control flow**. Instead of "always do A then B then C," the system does "do A, then ask the LLM what comes next, and follow its decision."

Compare a pipeline to an agent:

	Pipeline (Parts 1 & 2)	Agent (Part 3)
Control flow	Fixed sequence	LLM decides next step
Handles bad retrieval	Silently returns noise	Detects it, takes corrective action
Handles hallucination	No check	Detects it, regenerates
Can use web search	No	Yes, when local retrieval fails
Predictable execution path	Yes	No — depends on query + LLM judgment

The key word in the definition is *control flow*. An LLM call that just produces text is not agentic. An LLM call whose output is "relevant" or "irrelevant" — and those two values route the system down different paths — *is* agentic.

State Machines: The Mental Model

Before touching LangGraph, build the right mental model: an agent is a **state machine**.

A state machine has three things:

1. **State** — a snapshot of everything the system knows at this moment (the user's question, the documents found so far, the LLM's last answer, etc.)
2. **Nodes** — functions that read the current state, do some work, and return a partial update to the state
3. **Edges** — connections between nodes, either fixed ("always go from A to B") or conditional ("go from A to B or C, based on a function of the current state")

Each node transition potentially changes the state. The conditional edges look at the state to decide where to go. This is the core loop of every agent.

LangGraph: State Machines for LLM Agents

LangGraph is a Python library that implements this state machine pattern cleanly. Its three core building blocks map directly to the mental model above.

TypedDict State

The state is a `TypedDict` — a Python type annotation that gives names and types to every field in the shared state bag. Any node can read any field. Nodes return dicts containing only the fields they updated.

StateGraph

`StateGraph(MyState)` creates the graph and knows the shape of the state. You then add nodes and edges:

```
from langgraph.graph import StateGraph, END

graph_builder = StateGraph(GraphState)
graph_builder.add_node("retrieve", retrieve)          # fixed nodes
graph_builder.add_node("grade_documents", grade_documents)

graph_builder.add_edge("retrieve", "grade_documents") # fixed edge

graph_builder.add_conditional_edges(                  # conditional edge
    "grade_documents",
    route_after_grading,                             # function: state → next node name
    {
        "generate_answer": "generate_answer",
        "web_search": "web_search",
    }
)
```

`add_conditional_edges` takes three arguments: the source node, a routing function that maps state → node name string, and a dict translating those strings to actual node names (this indirection lets you rename nodes without updating the routing logic).

CRAG: Why the Original RAG Loop Fails

Parts 1 and 2 build a "fire and forget" pipeline: retrieve → generate. It has two known failure modes.

Failure mode 1 — bad retrieval silently poisons the answer. If the top-5 chunks returned by the retriever are all off-topic, the LLM is handed useless context. It will either produce a vague answer ("The provided context does not mention...") or hallucinate plausibly. There is no mechanism to notice this and try something else.

Failure mode 2 — the LLM hallucinates despite good retrieval. Even when relevant documents are in the context, LLMs sometimes ignore them and generate from their training weights. In creative tasks this is a feature; in a factual research assistant it is a bug.

CRAG (Corrective Retrieval-Augmented Generation) adds two LLM-as-judge steps:

1. **Grade retrieved documents:** for each retrieved chunk, ask an LLM "is this relevant to the query?" If too few are relevant, fall back to web search.
2. **Grade the generated answer:** after generation, ask an LLM "is this answer faithful to the context?" If not, loop back and regenerate.

The key insight is that the LLM is both the generator *and* the quality gatekeeper. An LLM is far better at judging relevance than any heuristic.

The GraphState TypedDict

Here is the complete state structure used in notebook 03:

notebooks/03_agentic_rag_langgraph.ipynb — GraphState

```
from typing import TypedDict

class GraphState(TypedDict):
    question: str          # the user's original query - never modified
    documents: list         # raw retrieval output (top-20 chunks)
    filtered_documents: list # after grading - only chunks judged relevant,
                           # or web search results if retrieval failed
    retrieval_grade: str    # "relevant" | "irrelevant"
                           # set by grade_documents, read by router
    generation: str         # the LLM's answer text
    faithfulness_grade: str # "faithful" | "hallucinated"
                           # set by grade_hallucination, read by router
    generation_attempts: int # incremented each time generate_answer runs;
                           # caps retries at MAX_REGENERATIONS=2
    execution_trace: list   # append-only log of every node's action -
                           # used for debugging and displaying "thinking steps"
```

Every node receives the full state and returns only the keys it changed. The state accumulates updates as it moves through the graph.

The 5-Node Graph

faithful OR attempts >= 2

What Each Node Does

retrieve: Issues the hybrid search query, runs the reranker, stores results in `documents` and `filtered_documents`. Sets `generation_attempts = 0`.

grade_documents: For each chunk in `documents`, calls the LLM with a binary relevance prompt. If at least one chunk is judged relevant, sets `retrieval_grade = "relevant"` and puts the passing chunks into `filtered_documents`. Otherwise sets `retrieval_grade = "irrelevant"`.

web_search (conditional): Only runs if `retrieval_grade == "irrelevant"`. Issues a DuckDuckGo search, fetches page content, appends it to `filtered_documents` so the generation node has something to work with.

generate_answer: Builds a prompt from the top-5 `filtered_documents` and the original `question`, calls the LLM, stores the answer in `generation`. Increments `generation_attempts`.

grade_hallucination: Passes the `generation` and the source chunks to the LLM judge. If the answer is not supported, sets `faithfulness_grade = "hallucinated"` and the graph loops back to `generate_answer`. If faithful (or if `generation_attempts` has hit the cap of 2), the graph terminates at `END`.

LLM-as-Judge: The Decision Maker

Both `grade_documents` and `grade_hallucination` rely on the same pattern: prompt an LLM to return structured JSON with a binary decision and a reason. The LLM's output routes the graph.

```
# grade_documents - per-chunk relevance grading prompt (simplified)
prompt = f"""Is the following document relevant to the question?
Question: {question}
Document: {chunk_text}
Answer JSON: {{ "relevant": true or false, "reason": "one sentence" }}
```

This is what makes the system "agentic" in the precise sense: the LLM's output (`true` or `false` in the JSON) determines which edge the graph follows.

Real Results

Agentic metrics vary by evaluation scope:

- Legacy 10-query runs on the smaller corpus showed strong faithfulness with minimal fallback.
- Current 4,000-baseline artifact (`artifacts/eval_results/03_agentic_rag_4000.json`) reports:
- `faithfulness_rate = 0.8`

- `web_search_rate = 0.8`

This highlights a practical point: the same architecture can show very different behavior when query difficulty and corpus conditions change.

The agentic loop does add latency — a query that triggers web search and one regeneration takes 3–5× longer than a straight pipeline call. This is the core tradeoff: correctness vs latency. For a research assistant where answer quality matters more than response time, it is a worthwhile trade.

Next step

With these concepts in hand — hybrid search, reranking, evaluation metrics, and the agentic graph — you have the vocabulary to understand every design decision in the three project notebooks. Part 1 starts from scratch with the simplest possible implementation; each part adds the components covered here.

4 Part 1 — Naive RAG

Part 1 — Naive RAG: Overview

Part 1 builds the simplest possible RAG pipeline: embed a corpus, store the vectors in FAISS, embed a query, retrieve the top-5 chunks, and hand them to a language model. No reranking, no keyword search, no self-correction loop. Just the bare bones.

This is intentional. The naive pipeline is fast to build, easy to reason about, and gives us a measured baseline. Every improvement in Parts 2 and 3 is justified by comparing against the numbers we record here.

What you build in this part

The pipeline has five stages. Each stage is a function in `src/ingest.py` — one file that all three notebooks share.

At the end of the notebook you run a 20-query evaluation and record the baseline metrics.

Current 4,000-paper baseline:

Metric	Value
Recall@5	0.050
Precision@5	0.010
MRR	0.0167

Historical legacy 600 baseline (for comparison): Recall@5 = 0.250, Precision@5 = 0.120, MRR = 0.2992.

These are your baseline. Part 2 improves them with hybrid retrieval and reranking. Part 3 builds an agent on top.

The notebook file

`notebooks/01_naive_rag.ipynb` is the runnable version of this tutorial section. Each cell corresponds to a stage in the pipeline. The notebook:

1. Calls `load_hf_papers()` to pull 4,000 ML papers from the `ccdv/arxiv-summarization` dataset.
2. Calls `chunk_documents()` to split each abstract into 512-character overlapping chunks.

3. Calls `embed_texts()` to generate 1024-dimensional vectors via Ollama.
4. Calls `build_faiss_index()` to construct the FAISS index in memory.
5. Calls `save_index_and_chunks()` to write the index to `artifacts/faiss_index/`.
6. Instantiates `DenseRetriever` and runs several example queries.
7. Defines a 20-query evaluation set and calls `compute_retrieval_metrics()`.
8. Saves results to `artifacts/eval_results/01_naive_rag_4000.json` for comparison across parts.

Definition — Naive RAG

"Naive" means a single retrieval pass with a single dense retriever and no post-processing. The term is used in the literature to distinguish the baseline from advanced variants that add reranking, query rewriting, or hybrid search.

Why start simple?

It is tempting to skip straight to the agentic architecture. Resist that temptation for three reasons:

1. **Debugging is easier.** With five functions, every failure has an obvious owner. If the answers are bad, you can tell in seconds whether the retriever is returning the wrong chunks or the LLM is ignoring good ones.
2. **The numbers are honest.** Reporting MRR = 0.441 in Part 2 is only meaningful if you also know the Part 1 baseline was 0.299. Without the naive run, the improvement is a number with no context.
3. **The shared index.** Notebooks 02 and 03 call `load_index_and_chunks()` and reuse the FAISS index you build here. You do the expensive embedding work once.

Run notebook 01 before notebooks 02 and 03

Notebooks 02 and 03 call `load_index_and_chunks()` and expect to find `artifacts/faiss_index/index.bin` and `artifacts/faiss_index/chunks.pkl`. These files are created by notebook 01. If you skip notebook 01 and run notebook 02 directly, you will get a `FileNotFoundError`.

What's next

The next page — [Loading Data](#) — walks through the `load_hf_papers()` function in detail: what the HuggingFace dataset contains, why we filter by ML keywords, and what a paper dict looks like before it enters the chunking step.

Loading Data

Before any embedding or indexing can happen, we need documents. This page explains where they come from, how they are filtered to stay on-topic, and what the data looks like when it arrives in Python.

The dataset — `ccdv/arxiv-summarization`

The corpus comes from `ccdv/arxiv-summarization` on HuggingFace. It contains roughly 203,000 academic papers scraped from ArXiv, each stored as a `(article, abstract)` pair. The `article` field is the full paper text; the `abstract` field is the structured summary the authors wrote.

We use only the `abstract` field because:

- Abstracts are self-contained. They summarise the paper's problem, method, and results in 150–400 words. A question about "how LoRA reduces memory" is answerable from the abstract alone.
- Abstracts are fast to embed. Processing full papers would require a much larger chunk budget and significantly longer indexing time.
- Noise is lower. Full papers contain section headings, references, and mathematical notation that degrade embedding quality.

Definition — Embedding quality

Embedding quality refers to how well a text's vector captures its meaning. Dense boilerplate text (reference lists, captions, repeated headers) can dilute the semantic signal in a vector, making it harder to distinguish a paper on "attention mechanisms" from one on "image segmentation."

The dataset spans all of ArXiv — physics, mathematics, chemistry, computer science. For a research assistant focused on ML and AI, papers about topology or organic chemistry add noise without adding relevant signal. The ML keyword filter solves this.

The `load_hf_papers()` function

```
def load_hf_papers(
    n_samples: int = 500,
    split: str = "train",
    ml_filter: bool = True,
    scan_multiplier: int = 10,
) -> list[dict]:
```

This function does three things:

1. Load a slice of the dataset

```
scan_size = n_samples * scan_multiplier
offset = 5000 # skip earliest rows (heavy math/stats bias)
raw = load_dataset(
    "ccdv/arxiv-summarization",
    split=f"{split}[{offset}:{offset + scan_size}]",
)
```

We ask for `n_samples * scan_multiplier` rows (default: $600 \times 10 = 6,000$) because only about 10–15% of all ArXiv papers are ML-related. The offset of 5,000 skips the earliest rows, which are disproportionately maths and statistics papers.

2. Apply the ML keyword filter

```
ML_KEYWORDS = [
    "neural network", "deep learning", "machine learning", "transformer",
    "attention mechanism", "language model", "reinforcement learning",
    "classification", "object detection", "generative model", "diffusion",
    "fine-tuning", "pre-training", "bert", "gpt", "llm", "embedding",
    # ... 14 more keywords
]

if ml_filter:
    abstract_lower = abstract.lower()
    if not any(kw in abstract_lower for kw in ML_KEYWORDS):
        continue
```

This is OR logic — a paper is kept if its abstract contains *any* of the listed keywords. The list covers the major subfields: NLP (`bert`, `gpt`, `language model`), computer vision (`object detection`, `convolutional`), generative models (`diffusion`, `generative model`), and general ML (`gradient descent`, `training`, `benchmark`).

3. Construct normalised paper dicts

The HuggingFace dataset does not always have a clean `title` field. We extract the first sentence of the abstract as a stand-in title:

```
first_sentence = abstract.split(".")[0].strip()
title = first_sentence[:120] + ("..." if len(first_sentence) > 120 else "")
paper_id = f"arxiv_{split}_{offset + idx:05d}"
```

What a paper dict looks like

Every paper is stored as a plain Python dict. Here is a representative example:

```
{
  "id": "arxiv_train_05042",
  "title": "We propose a novel attention mechanism for transformer models that...",
  "abstract": "We propose a novel attention mechanism for transformer models that "
    "dynamically weights each head based on task context. Our method, "
    "HydraHead, reduces inference cost by 23% while maintaining benchmark "
    "accuracy on GLUE and SuperGLUE. Experiments on eight downstream "
    "classification tasks confirm that head specialisation is learnable "
    "without additional supervision.",
  "category": "cs.AI",
  "url": "https://arxiv.org/abs/arxiv_train_05042",
}
```

The `id` field is the primary key. It links paper dicts to their chunks (which carry a `paper_id` field) and to evaluation ground-truth (the `relevant_ids` list in each eval query).

The arxiv.org primary path

`load_hf_papers()` is the fallback. The primary function `load_arxiv_papers()` tries to fetch from `arxiv.org` first (filtered to `cs.CL`, `cs.AI`, `cs.LG`). If the network is unavailable, it automatically falls back to `load_hf_papers()`. For offline use or reproducibility, call `load_hf_papers()` directly.

What's next

Now that we have 600 paper dicts, the next step is to split each abstract into smaller pieces that the embedding model can handle well. Head to [Chunking](#) to see how the 512-character window strategy works and why overlap matters.

Chunking

Before we embed anything, we need to decide what unit of text to embed. This page explains why we don't embed whole abstracts, what the 512/64 parameters mean, and how `chunk_documents()` implements overlapping windows.

Why chunk at all?

Short answer: granularity. A user asking "how does LoRA reduce memory?" wants the two sentences that explain the rank-decomposition trick — not an entire 300-word abstract that spends half its words on motivation and evaluation.

When you embed a full abstract, the resulting vector represents the centroid of all the ideas in the document. A paper that covers LoRA, QLoRA, and adapter modules will produce a single vector that sits roughly equidistant from all three topics. If the query is about LoRA specifically, the full-document vector may not be the closest match.

By splitting the abstract into smaller pieces, each chunk's vector captures a narrower slice of meaning. The retriever can surface the exact passage that answers the question, not just the paper that roughly covers the topic.

Abstracts are already short

At 150–400 words, an ArXiv abstract typically produces only 1–3 chunks at 512 characters. This is intentionally coarse — we are not splitting paragraphs mid-sentence, we are keeping full semantic units while still giving the embedding model a focused input. For full papers (methods, results, discussion sections), you would use smaller chunks: 256–384 characters.

The 512 / 64 parameters

```
DEFAULT_CHUNK_SIZE      = 512    # target characters per chunk (~128 tokens)
DEFAULT_CHUNK_OVERLAP = 64      # characters shared between consecutive chunks
```

Chunk size — 512 characters

At roughly 4 characters per token, 512 characters is about 128 tokens. This is well within `qwen3-embedding:0.6b`'s context window and gives the model a meaningful unit of text to work with — usually one or two sentences of a typical abstract paragraph.

Overlap — 64 characters

Overlap is the number of characters that are repeated at the end of one chunk and the start of the next. Consider what happens without overlap at a chunk boundary:

... The model is trained using a contrastive [BOUNDARY] objective that pushes representations of the same image under different augmentations closer together ...

Without overlap, the phrase "contrastive objective" is split across two chunks. A query about "contrastive objectives in self-supervised learning" might match neither chunk strongly because neither chunk contains the full phrase. With 64-character overlap, the end of the first chunk includes enough context for the phrase to survive intact in at least one of the two chunks.

Visualised overlap:

```
Abstract text: |----- abstract (400 chars) -----|

Chunk 0:      |<--- 512 chars --->|
               ^--- boundary
Chunk 1:      |<--- 512 chars --->|
               |<-64->| overlap
```

The step between chunk starts is `chunk_size - chunk_overlap = 512 - 64 = 448` characters.

Choosing your own parameters

For production use, tune chunk size based on two constraints: (1) the embedding model's max input length, and (2) the typical length of a relevant passage in your domain. Overlap of 10–15% of chunk size is a good starting point (64 / 512 $\approx$ 12.5% here). Larger overlap = more chunks = more index memory + slower embedding time.

The `chunk_documents()` function

```
def chunk_documents(
    papers: list[dict],
    chunk_size: int = DEFAULT_CHUNK_SIZE,
    chunk_overlap: int = DEFAULT_CHUNK_OVERLAP,
) -> list[dict]:
```

The implementation is a simple sliding window over characters:

```
step = chunk_size - chunk_overlap    # 448
start = 0
chunk_idx = 0
while start < len(text):
    end = min(start + chunk_size, len(text))
    chunk_text = text[start:end].strip()
    if len(chunk_text) > 50:    # skip tiny trailing fragments
        chunks.append({...})
        chunk_idx += 1
    start += step
```

The `len(chunk_text) > 50` guard discards the short trailing fragment that appears when a text's length is not a clean multiple of the step size. A 5-word fragment at the end of an abstract carries almost no retrievable information.

What a chunk dict looks like

```
{
  "chunk_id":      "arxiv_train_05042_chunk_0",
  "paper_id":      "arxiv_train_05042",
  "title":         "We propose a novel attention mechanism for transformer models...",
  "category":      "cs.AI",
  "text":          "We propose a novel attention mechanism for transformer models that "
                  "dynamically weights each head based on task context. Our method, "
                  "HydraHead, reduces inference cost by 23% while maintaining ...",
  "chunk_index": 0,
}
```

The `chunk_id` is unique across the entire corpus. The `paper_id` links back to the source paper — this is what the evaluator uses to decide whether a retrieved chunk counts as a hit. The `text` field is what gets passed to `embed_texts()`.

For a 600-paper corpus with abstracts averaging ~300 characters, `chunk_documents()` typically produces around 700–900 chunks total. Most abstracts produce one chunk; longer ones produce two.

What's next

With chunks in hand, the next step is turning each chunk's text into a 1024-dimensional vector. Head to [Embedding and Indexing](#) to see how `embed_texts()` batches calls to Ollama, why we L2-normalise the vectors, and how `build_faiss_index()` stores them for fast retrieval.

Embedding and Indexing

After chunking, each chunk is a plain string. To make it searchable by meaning rather than by keyword, we convert it to a dense vector — an embedding. This page covers the three functions that turn a list of strings into a queryable FAISS index, and how the artifacts are persisted so that notebooks 02 and 03 do not have to re-embed the corpus.

`embed_texts()` — batched calls to Ollama

```
def embed_texts(
    texts: list[str],
    model: str = EMBED_MODEL_LITE,    # "qwen3-embedding:0.6b"
    batch_size: int = 32,
) -> np.ndarray:
```

The function iterates over the chunk list in batches of 32, calls `ollama.embed()` for each batch, collects the results, and returns a single numpy array:

```
for i in tqdm(range(0, len(texts), batch_size), desc=f"Embedding ({model})"):
    batch = texts[i : i + batch_size]
    response = ollama.embed(model=model, input=batch)
    all_embeddings.extend(response["embeddings"])

embeddings = np.array(all_embeddings, dtype=np.float32)
```

Why batch size 32? A single `ollama.embed()` call has a fixed overhead for loading the model into the inference engine. Processing 32 texts per call amortises that overhead without asking the Ollama server to hold hundreds of inputs in memory at once. On an 8GB GPU (RTX 4060), batch size 32 keeps VRAM usage comfortably below the limit for `qwen3-embedding:0.6b`.

Why float32? FAISS expects float32 arrays. Using float16 would halve memory but requires an explicit cast before every FAISS call. Float32 keeps the code simple.

L2 normalisation — why it matters

Immediately after collecting the raw embeddings, `embed_texts()` normalises every vector:

```
norms = np.linalg.norm(embeddings, axis=1, keepdims=True)
embeddings = embeddings / np.maximum(norms, 1e-10)
```

This divides each vector by its own Euclidean magnitude, producing unit-length vectors. The `np.maximum(..., 1e-10)` guard prevents division-by-zero on a zero vector (which should never occur for real text, but defensive code is good practice).

After normalisation, the dot product (inner product) of two vectors equals their cosine similarity:

```
dot(a, b) = |a| × |b| × cos(θ)
           = 1 × 1 × cos(θ)    # after L2 normalisation
           = cos(θ)
```

Cosine similarity measures the angle between two vectors, ignoring their magnitude. This is what we want for semantic search: two chunks that discuss the same concept should have a high cosine score regardless of whether one is 100 characters and the other is 400.

Definition – Cosine similarity

Given two unit vectors, cosine similarity ranges from -1 (opposite directions) to +1 (identical direction). For text embeddings, values above 0.7 typically indicate strong semantic overlap; values near 0 indicate unrelated content.

`build_faiss_index()` — creating `IndexFlatIP`

```
def build_faiss_index(embeddings: np.ndarray) -> faiss.IndexFlatIP:
    n, dim = embeddings.shape
    index = faiss.IndexFlatIP(dim)
    index.add(embeddings)
    logger.info(f"Built FAISS index: {n} vectors, dimension {dim}")
    return index
```

`IndexFlatIP` is FAISS's exact inner-product index. "Flat" means all vectors are stored sequentially in memory and a query triggers a brute-force scan over every stored vector. For 700–900 vectors at 1024 dimensions, this scan completes in under 1 millisecond — exact search is entirely practical at this scale.

The alternative — an approximate index like `IndexIVFFlat` or `IndexHNSW` — would be faster at scale (millions of vectors) but adds a training step, introduces recall loss, and is harder to reason about. We use the flat index because correctness and simplicity matter more here than sub-millisecond latency.

When to switch to an approximate index

The rule of thumb: switch from `IndexFlatIP` to `IndexIVFFlat` or `IndexHNSW` when your corpus exceeds ~100,000 vectors and query latency becomes noticeable. For a 600-paper corpus producing under 1,000 chunks, exact search is the right choice.

`save_index_and_chunks()` — persisting to disk

```
def save_index_and_chunks(
    index: faiss.IndexFlatIP,
    chunks: list[dict],
    base_path: Path,
) -> None:
    faiss.write_index(index, str(index_path))
    with open(chunks_path, "wb") as f:
        pickle.dump(chunks, f)
```

Two files are written together:

File	What it contains
artifacts/faiss_index/index.bin	The FAISS binary — vectors only, no text
artifacts/faiss_index/chunks.pkl	The chunk dicts — text, metadata, IDs

The FAISS index maps integer positions (0, 1, 2, ...) to vectors. The chunks list maps those same integer positions to chunk text and metadata. They are always saved and loaded together. Saving one without the other would produce a retriever that returns vectors with no associated text — it would crash on the first query.

Notebooks 02 and 03 call `load_index_and_chunks()` to skip the 60-second embedding step:

```
index, chunks = load_index_and_chunks(base_path=ARTIFACTS_DIR / "faiss_index")
```

This is the payoff for keeping all ingestion logic in `src/ingest.py`: the index is built exactly once and shared across the entire tutorial series.

What's next

With the index on disk, we are ready to query it. The next page — [Retrieval and Generation](#) — covers the `DenseRetriever` class, how a user question becomes a FAISS search call, and how the retrieved chunks are assembled into a prompt for `granite4.1:8b`.

Retrieval and Generation

With the FAISS index saved to disk, the pipeline is ready to answer questions. This page covers two things: how the `DenseRetriever` class turns a user question into a ranked list of chunks, and how the `naive_rag()` function assembles those chunks into a prompt and calls `granite4.1:8b` for the final answer.

The `DenseRetriever` class

`DenseRetriever` lives in `src/retriever.py`. Its job is to wrap the FAISS index and the chunks list behind a clean `.retrieve(query, k)` interface.

```
class DenseRetriever:
    def __init__(
        self,
        index,                # faiss.IndexFlatIP from build_faiss_index()
        chunks: list[dict],   # same list saved by save_index_and_chunks()
        embed_model: str = EMBED_MODEL_PRIMARY,
    ) -> None:
        self.index = index
        self.chunks = chunks
        self.embed_model = embed_model
```

The two constructor arguments — `index` and `chunks` — are the exact objects returned by `load_index_and_chunks()`. They share an implicit contract: `chunks[i]` is the text that produced the vector at row `i` in the index.

Always use the same embedding model

The `embed_model` parameter must match the model used to build the index. If you embed the corpus with `qwen3-embedding:0.6b` and then query with `qwen3-embedding:4b`, the vectors live in different vector spaces — the similarity scores will be meaningless and retrieval will silently break. The code logs a reminder but cannot enforce this at runtime.

`embed_query()` and `faiss.search()`

When `.retrieve()` is called, it performs two steps:

Step 1 — embed the query

```
query_vec = embed_query(query, model=self.embed_model)
```

`embed_query()` is defined in `src/ingest.py`. It calls `ollama.embed()` with a single string, L2-normalises the result, and returns a float32 array of shape `(1, 1024)`. The shape `(1, 1024)` rather than `(1024,)` is deliberate — FAISS's `.search()` expects a 2D input where the first dimension is the number of queries.

Step 2 — search the FAISS index

```
scores, indices = self.index.search(query_vec, k)
```

FAISS scans all stored vectors, computes the inner product between `query_vec` and each one, and returns the `k` highest scores. Because the vectors are L2-normalised, inner product equals cosine similarity. `scores[0]` is a float array of shape `(k,)` and `indices[0]` is the corresponding integer row positions into the chunks list.

Step 3 — map back to chunk dicts

```
for score, idx in zip(scores[0], indices[0]):
    if idx == -1:
        continue
    chunk = dict(self.chunks[idx])
    chunk["score"] = float(score)
    chunk["retriever"] = "dense"
    results.append(chunk)
```

The `idx == -1` guard handles the edge case where the index contains fewer than `k` vectors. Each returned chunk is a copy of the original dict, augmented with a `"score"` key so the caller can see how similar each result was.

The RAG prompt template

The retrieved chunks are assembled into a structured prompt before being passed to the LLM:

```
RAG_PROMPT = """You are a research assistant specialising in machine learning and AI.
Answer the user's question using ONLY the information provided in the context below.
If the context does not contain enough information to answer, say:
"The retrieved documents do not contain enough information to answer this question."
Do not use any knowledge beyond what is in the context.

Context:
{context}

Question: {question}

Answer: """
```

The `ONLY` instruction is the most important line in the template. Without it, `granite4.1:8b` will blend retrieved evidence with its parametric knowledge — producing answers that sound correct but may include facts not present in the corpus. The explicit fallback phrase also matters: it gives the model a graceful exit when the retrieved context is genuinely unhelpful, rather than forcing it to hallucinate.

Each retrieved chunk is formatted as a numbered document block:

```
context_parts = []
for i, chunk in enumerate(retrieved, 1):
    context_parts.append(f"[Document {i}] {chunk['title']} \n {chunk['text']}")
context = "\n\n".join(context_parts)
```

The `[Document N]` prefix helps the model distinguish between sources and occasionally reference them in its answer.

`ollama.chat()` — the generation call

```
response = ollama.chat(
    model=llm_model,
    messages=[{"role": "user", "content": prompt}],
)
answer = response["message"]["content"].strip()
```

`ollama.chat()` is a blocking synchronous call. It sends the full prompt to `granite4.1:8b` running locally and waits for the complete response. For a typical RAG answer (100–300 words), this takes 3–8 seconds on an RTX 4060.

The return value from `naive_rag()` bundles the answer with its provenance:

```
return {
    "question": query,
    "answer": answer,
    "contexts": [c["text"] for c in retrieved], # raw chunk texts
    "sources": [c["title"] for c in retrieved], # paper titles
    "scores": [c["score"] for c in retrieved], # similarity scores
}
```

Keeping `contexts` and `sources` in the return dict is important for evaluation: the faithfulness scorer in `src/evaluator.py` needs the raw retrieved texts to check whether the answer is grounded in them.

What's next

Now that we can retrieve and generate, the next question is: how good is it? Head to [Evaluation](#) to see how the 20-query eval set is constructed, what `compute_retrieval_metrics()` computes, and what the three metric numbers actually mean.

Evaluation

Building a RAG pipeline is the easy part. Knowing whether it is any good requires a structured evaluation. This page covers the 20-query eval set, the ground-truth construction method, the three metrics, and why each design choice matters.

The 20-query eval set

The evaluation set contains 20 questions that span the range of topics in the corpus: attention mechanisms, contrastive learning, LLM inference efficiency, diffusion models, calibration, LoRA, RAG itself, chain-of-thought prompting, and more. Each question has a `relevant_ids` list — the paper IDs that a retriever should return to be considered correct.

```
eval_queries = [
    {
        "question": "What is attention head heterogeneity in transformers?",
        "relevant_ids": find_relevant_ids_by_keywords(
            ["attention head", "head heterogeneity", "hydrahead", "head specialization"],
            papers,
        ),
    },
    {
        "question": "How does contrastive learning work?",
        "relevant_ids": find_relevant_ids_by_keywords(
            ["contrastive learning", "contrastive loss", "simclr", "nce loss"],
            papers,
        ),
    },
    # ... 18 more queries
]
```

The `relevant_ids` are derived from the actual corpus at runtime, not hardcoded. This means the eval set adapts to whatever 600 papers were loaded — a query only has relevant papers if those papers are actually in the corpus.

`find_relevant_ids_by_keywords()` — multi-keyword OR logic

The ground-truth function accepts a list of keywords and returns paper IDs where any keyword appears in the title or abstract:

```
def find_relevant_ids_by_keywords(
    keywords: list[str], papers: list, top_n: int = 3
) -> list[str]:
    matched = []
    for p in papers:
        combined = (p["title"] + " " + p["abstract"]).lower()
        if any(kw.lower() in combined for kw in keywords):
            matched.append(p["id"])
    return matched[:top_n]
```

This is OR logic — a paper is relevant if it contains *any* of the keywords. This design choice has a significant impact on eval quality. Consider the alternative: a single keyword like "attention head" might match zero papers in a given 600-paper sample. A query with zero relevant papers cannot contribute meaningfully to Recall or Precision — both would be zero regardless of what the retriever returns. Over 20 queries, several zero-ground-truth queries would drag every metric down and tell us nothing about retrieval quality.

Why multi-keyword OR captures synonyms

The query "How does attention head heterogeneity affect transformers?" could be answered by papers that use any of: "attention head," "head heterogeneity," "HydraHead," or "head specialization." These are different surface forms for the same concept. The OR list ensures that papers using any of these forms are counted as relevant — mirroring how a human expert would evaluate retrieval quality.

compute_retrieval_metrics() — the three numbers

```
from src.evaluator import compute_retrieval_metrics

naive_retrieval_metrics = compute_retrieval_metrics(
    queries=eval_queries,
    retriever=dense_retriever,
    k=5,
)
```

For each query, the function calls `retriever.retrieve(query, k=5)`, extracts the `paper_id` from each result, and computes three metrics:

Recall@5 — did the right papers appear in the top 5?

$$\text{Recall@5} = |\text{relevant n top-5}| / |\text{relevant}|$$

If a query has 2 relevant papers and the retriever returns both in the top 5, Recall@5 = 1.0. If it returns only one, Recall@5 = 0.5. Recall measures completeness — did we find everything that should have been found?

Precision@5 — how many of the top 5 were actually relevant?

$$\text{Precision@5} = |\text{relevant n top-5}| / 5$$

If 1 of the 5 returned chunks is relevant, Precision@5 = 0.20. Precision measures noise — how many of the results the LLM has to read are actually useful?

MRR (Mean Reciprocal Rank) — how high up was the first relevant result?

$$\text{MRR} = 1 / \text{rank_of_first_relevant}$$

First hit at rank	Contribution to MRR
1	1.000
2	0.500
3	0.333
5	0.200
Not found	0.000

MRR is averaged across all 20 queries. It captures whether the most relevant document is at the top — critical for generation quality, because the LLM reads the context in order and pays more attention to earlier documents.

Definition — Why MRR over MAP?

Mean Average Precision (MAP) rewards returning all relevant documents early. MRR only cares about the first relevant document. For RAG, MRR is more appropriate because the LLM typically uses the top-1 or top-2 chunks most heavily when generating an answer. Getting one strong relevant chunk at rank 1 matters more than having all relevant chunks somewhere in the top 10.

What's next

With the metrics defined and computed, the final page — [Results and Limitations](#) — presents the actual numbers from the 20-query run, explains why they are lower than the earlier 5-query results, and identifies the specific failure modes of naive RAG that Part 2 is designed to fix.

Results and Limitations

This page presents the real numbers from the Part 1 evaluation, explains honestly why the eval was redesigned (and why the new numbers look worse), and identifies the specific failure modes of naive dense retrieval that motivate every change made in Part 2.

The results

Running `compute_retrieval_metrics()` over 20 queries with `k=5` on a 600-paper corpus produces:

Metric	Value	What it means
Recall@5	0.250	In 1 in 4 queries, at least one relevant paper appeared in the top 5
Precision@5	0.120	On average, 0.6 of the 5 retrieved chunks were relevant
MRR	0.299	The first relevant result appeared, on average, around rank 3–4

These are your baseline numbers. Every improvement in Part 2 will be judged against them.

Why the numbers look lower than the earlier 5-query results

You may have seen earlier notebook cells that reported much higher numbers:

Eval set	Recall@5	Precision@5	MRR
Old — 5 queries, 300 papers	0.533	0.240	0.417
New — 20 queries, 600 papers	0.250	0.120	0.299

The drop is almost entirely explained by the eval set redesign, not by a change in retriever quality. Three specific factors account for the difference:

1. More queries, more variance exposure

With 5 queries, a single lucky result moves Recall by 20 percentage points. The 5-query set happened to contain several queries where the relevant papers were densely represented in the 300-paper corpus — which inflated all three metrics. At 20 queries, the noise averages out and the true performance of the retriever becomes visible.

2. Larger corpus — harder retrieval

300 papers produce roughly 350–400 chunks. 600 papers produce roughly 700–900 chunks. Doubling the index size doubles the competition for each query: the relevant chunk now has to outscore twice as many irrelevant candidates. All else being equal, retrieval precision falls as the corpus grows.

3. Harder queries in the expanded set

The original 5 queries were implicitly chosen to match the small corpus well. The 20-query set includes topics that are less well-represented: web search integration for RAG, LLM self-correction, speculative decoding, and others. These queries stress the retriever more.

The 5-query numbers were not dishonest — they were on a different setup

Reporting both sets of numbers and explaining the difference is exactly the right approach. A reader who only saw 0.533 and then ran the pipeline on their own 600-paper corpus would be confused when they saw 0.250. Honest evaluation means being explicit about what the eval set covers and what it does not.

Limitations of naive RAG

The numbers expose three structural weaknesses in the naive pipeline.

Limitation 1 — Dense retrieval misses exact terms

`qwen3-embedding:0.6b` is trained to capture semantic similarity. It excels at synonyms and paraphrases. But a query for "RLHF" or "InstructGPT" requires exact-term matching. If the embedding model does not place those specific strings close to their conceptual neighbours, the relevant papers will not rank highly. BM25 — introduced in Part 2 — handles exact-term queries correctly because it operates on token frequency, not vector geometry.

Limitation 2 — No hallucination check

The `naive_rag()` function hands the retrieved context to `granite4.1:8b` and trusts it. There is no check on whether the answer is actually supported by the context. When the retrieved chunks are only weakly relevant, the model has a choice: admit ignorance (following the prompt instruction) or blur the line between retrieved evidence and parametric knowledge. In practice, it often does the latter. The agentic pipeline in Part 3 adds a faithfulness scorer to catch this.

Limitation 3 — No feedback loop

If the retrieval is poor, there is no mechanism to try again. The pipeline runs once: retrieve, prompt, generate. A single query with a vague phrasing ("what are some recent methods?") will retrieve a random-looking set of chunks because the query vector has no sharp semantic target. Agentic RAG solves this with query rewriting and iterative retrieval.

What these failures motivate

Failure mode	Fix in Part 2	Fix in Part 3
Dense misses exact terms	BM25 + hybrid search	—
Noisy top-5 (irrelevant chunks)	Cross-encoder reranker	—
Vague queries	Query rewriting	Agent decides whether to rephrase
No grounding check	—	LLM-as-judge faithfulness scorer
No fallback when corpus is empty	—	Web search fallback

The metrics in Part 2 will quantify exactly how much each of these fixes contributes. Part 3 will show how a state machine can combine all of them into a self-correcting loop.

The honest baseline is valuable

MRR = 0.299 is not a failure — it is a starting point with a clear measurement. Many production RAG systems are deployed without any retrieval evaluation at all. Knowing your baseline means you can tell whether a change is actually an improvement.

What's next

You have completed Part 1. The pipeline works, the baseline is measured, and the failure modes are understood. Head to **Part 2 — Advanced RAG** to see how hybrid retrieval and reranking move MRR from 0.299 to 0.441.

5 Part 2 — Advanced RAG

Part 2 — Advanced RAG Overview

Part 1 gave us a working RAG pipeline: embed the corpus, search with FAISS, generate with the LLM. It answers questions. But when you measure it honestly against 20 diverse queries, it only achieves an MRR of 0.299. That means the most relevant paper lands at rank 3–4 on average, and sometimes it doesn't appear in the top 5 at all.

Part 2 diagnoses why, then fixes it — without changing the LLM, the corpus, or the chunking strategy. Everything we improve is in the retrieval layer.

What Part 1 gets wrong

Semantic (dense) search is good at paraphrase. Ask "how do LLMs generate text?" and it finds papers about autoregressive decoding even though neither phrase appears verbatim in the other. That's the strength of embeddings.

But ML papers are full of exact terminology: model names (`Qwen3`), method names (`LoRA` , `FlashAttention`), benchmark names (`SQuAD` , `MMLU`). When a user queries "BM25 for document ranking", a semantic model might return papers about neural information retrieval that are semantically close but not what the user meant. The exact string "BM25" is a strong signal — and a cosine similarity search has no way to exploit it.

Retrieval is the biggest lever

Swapping the LLM from Llama 3 to GPT-4 on a broken retrieval pipeline doesn't fix bad answers — it generates better-sounding wrong answers. The document that isn't retrieved cannot be cited.

Three layers added in Part 2

Part 2 adds three improvements in sequence, each measured independently:

Each layer is a separate class in `src/retriever.py`: `BM25Retriever`, `HybridRetriever`, and `Reranker`. You can swap them in and out individually, which is exactly how the results table is produced.

What the numbers say

Here is the full 20-query evaluation across all strategies:

Strategy	Recall@5	Precision@5	MRR
Dense baseline	0.250	0.120	0.299
BM25 improved tokenisation	0.367	0.190	0.441
Hybrid alpha=0.7	0.267	0.130	0.308
Hybrid RRF	0.267	0.130	0.287
Hybrid RRF + Rerank	0.333	0.170	0.363

The single most impactful change — improving BM25 tokenisation — raises MRR from 0.299 to 0.441. That's a 47% gain from a 3-line code change.

There's also a surprising result: RRF (Reciprocal Rank Fusion), the theoretically superior rank-based fusion method, does not beat the alpha-blend fusion on this corpus. The evaluation page explains why in detail.

Where this leaves us

After Part 2, retrieval quality is meaningfully better. But the pipeline is still single-hop — it runs one retrieval pass and trusts whatever comes back. If retrieval fails silently (the right paper isn't in the top 5), the LLM generates a plausible-sounding answer with no warning.

Part 3 fixes this by adding a self-correction loop: the system grades its own retrieved documents, falls back to web search when the corpus is insufficient, grades its own answers for hallucinations, and retries if something goes wrong.

Continue reading Part 2:

- [BM25 in Practice](#) — the tokenisation problem and how to fix it
- [Hybrid Retrieval](#) — alpha fusion and RRF explained side by side
- [Cross-Encoder Reranking](#) — two-stage retrieve-then-rerank
- [Evaluation](#) — the 20-query benchmark setup and results
- [Results and Limits](#) — full comparison table and what's next

BM25 in Practice

BM25 (Best Match 25) is a classical keyword-scoring algorithm that has been the gold standard in information retrieval since 1994. Before neural embeddings existed, BM25 was how search engines ranked documents. It is fast, interpretable, and exceptionally good at one thing: scoring documents that share exact words with the query.

This page walks through the `BM25Retriever` class in `src/retriever.py`, explains the tokenisation bug that limited its performance in the original version, and shows the fix that produced the biggest single improvement in the entire benchmark.

How BM25 scores a document

For each query term `t`, BM25 computes:

$$\text{score}(D, Q) = \sum_t \text{IDF}(t) \times (\text{tf}(t, D) \times (k_1 + 1)) / (\text{tf}(t, D) + k_1 \times (1 - b + b \times |D| / \text{avgdl}))$$

Where:

- $\text{IDF}(t) = \log((N - \text{df}(t) + 0.5) / (\text{df}(t) + 0.5))$ — rare terms score higher
- $\text{tf}(t, D)$ = how many times term `t` appears in document `D`
- $|D|$ = document length; `avgdl` = average document length across the corpus
- $k_1=1.5$, $b=0.75$ are the standard Okapi BM25 constants

In plain English: a term contributes high score when it appears often *in this document* (high `tf`) but rarely *across all documents* (high `IDF`). Long documents are penalised by the length normalisation term $b \times |D| / \text{avgdl}$.

This is why BM25 complements dense retrieval. Dense embeddings capture meaning regardless of exact words. BM25 rewards exact term overlap — which is exactly what you want when a query contains specific technical terms like `LoRA`, `RLHF`, or `SQuAD`.

The BM25Retriever class

```

class BM25Retriever:
    def __init__(self, chunks: list[dict]) -> None:
        self.chunks = chunks

        # OLD tokenisation (whitespace only - kept for reference):
        # tokenised_corpus = [chunk["text"].lower().split() for chunk in chunks]

        # IMPROVED tokenisation (lowercase + strip punctuation + stop words):
        tokenised_corpus = [_tokenise(chunk["text"]) for chunk in chunks]
        self.bm25 = BM25Okapi(tokenised_corpus)
        logger.info(f"Built BM25 index over {len(chunks)} chunks.")

    def retrieve(self, query: str, k: int = 5) -> list[dict]:
        # OLD: query_tokens = query.lower().split()
        # IMPROVED: same tokeniser as the corpus - must match for consistent scoring
        query_tokens = _tokenise(query)
        scores = self.bm25.get_scores(query_tokens)

        top_k_indices = np.argsort(scores)[::-1][:k]

        results = []
        for idx in top_k_indices:
            chunk = dict(self.chunks[idx])
            chunk["score"] = float(scores[idx])
            chunk["retriever"] = "bm25"
            results.append(chunk)

        return results

```

The constructor builds the BM25 index once — `BM25Okapi(tokenised_corpus)` tokenises and stores term frequencies for every chunk. At query time, `bm25.get_scores(query_tokens)` returns a raw score for every document in the corpus as a numpy array, which is then sorted to get the top-k.

Index cost is $O(\text{corpus})$

Building the BM25 index is a one-time $O(N)$ operation over the corpus. Each query is $O(|\text{query terms}| \times N)$ for score computation. For 600 papers and typical short queries, this is fast enough that it does not need caching.

The old tokenisation: three failure modes

The original implementation used Python's default whitespace split:

```

# OLD - do not use
tokenised_corpus = [chunk["text"].lower().split() for chunk in chunks]
query_tokens = query.lower().split()

```

This looks harmless but introduces three problems:

Failure mode 1 — Punctuation creates phantom tokens. "attention." and "attention" are different tokens under whitespace split. If the query contains `attention` but the corpus contains `attention.` (end of sentence), BM25 scores zero for that term even though they're the same word. In a paper abstract, virtually every noun appears at least once with trailing punctuation.

Failure mode 2 — Stop words consume scoring budget. Words like `the`, `is`, `of`, `in` appear in every document with high term frequency but near-zero IDF (since they appear in *all* documents, $\log((N - N + 0.5)/(N + 0.5)) \approx 0$). Their direct contribution to BM25 is negligible. The problem is that they pollute the token set: when the query is "what is the attention mechanism", half the query tokens are stop words that score near-zero everywhere and add noise to the final ranking.

Failure mode 3 — Mixed case breaks rare-term matching. ML papers often use mixed case: "Transformer" at the start of a sentence, "transformer" mid-sentence. Under whitespace split + lowercase, these are the same. But any uppercase-only tokenisation (even accidental) would split them.

The new `_tokenise()` function

```
BM25_STOP_WORDS: frozenset[str] = frozenset({
    "the", "a", "an", "is", "are", "was", "were", "be", "been", "being",
    "have", "has", "had", "do", "does", "did", "will", "would", "could",
    "should", "may", "might", "shall", "can", "of", "in", "on", "at",
    "to", "for", "with", "by", "from", "as", "this", "that", "these",
    "those", "it", "its", "we", "our", "they", "their", "which", "who",
    "and", "or", "but", "not", "no", "nor", "so", "yet", "both", "each",
    "about", "than", "more", "also", "such", "into", "its", "over",
})

def _tokenise(text: str) -> list[str]:
    """Lowercase, strip non-alphanumeric chars, remove stop words and single-char tokens."""
    tokens = re.sub(r"[^a-z0-9]", " ", text.lower()).split()
    return [t for t in tokens if t not in BM25_STOP_WORDS and len(t) > 1]
```

Three steps in one line:

1. `text.lower()` — case-normalise the whole string first
2. `re.sub(r"[^a-z0-9]", " ", ...)` — replace every non-alphanumeric character with a space, so `attention.` becomes `attention` and hyphens in compound terms are treated as separators
3. Filter: drop tokens that are stop words or single characters

The stop-word list is intentionally narrow — only function words and auxiliary verbs. Technical nouns like `not` in "not pre-trained" are excluded deliberately because negation can matter for relevance.

Corpus and query must use the same tokeniser

BM25 scoring requires that query tokens and corpus tokens are in the same vocabulary. If you tokenise the corpus with `_tokenise()` but send the query through `.lower().split()`, you'll be searching for `"attention."` in an index that contains `"attention"` — and scoring zero for every document. The `retrieve()` method calls `_tokenise(query)` for exactly this reason.

Impact

This change — three lines of code — produced the biggest single improvement in the 20-query benchmark:

Tokenisation	Recall@5	MRR
Dense baseline	0.250	0.299
BM25 (whitespace split)	0.300	0.333
BM25 (improved <code>_tokenise</code>)	0.367	0.441

MRR jumps from 0.299 (dense baseline) to 0.441 (+47%). The improvement is entirely from better preprocessing — the BM25 algorithm, the corpus, and the queries are identical.

Hybrid Retrieval

Dense and BM25 retrieval have complementary failure modes. Dense search misses exact technical terms; BM25 misses paraphrase and semantic similarity. The natural response is to run both and combine their results — that's hybrid retrieval.

But combining two ranked lists with different score scales is non-trivial. This page walks through both fusion strategies in `src/retriever.py`, explains the alpha-ablation experiment, and looks at a surprising result: the theoretically more robust method (RRF) did not beat the simpler one on this corpus.

The HybridRetriever class

```
class HybridRetriever:
    def __init__(
        self,
        dense: DenseRetriever,
        bm25: BM25Retriever,
        alpha: float = 0.7,
        fusion: str = "alpha", # "alpha" or "rrf"
        rrf_k: int = 60,
    ) -> None:
        self.dense = dense
        self.bm25 = bm25
        self.alpha = alpha
        self.fusion = fusion
        self.rrf_k = rrf_k

    def retrieve(self, query: str, k: int = 10) -> list[dict]:
        fetch_k = k * 2

        dense_results = self.dense.retrieve(query, k=fetch_k)
        bm25_results = self.bm25.retrieve(query, k=fetch_k)

        if self.fusion == "rrf":
            return self._rrf_fusion(dense_results, bm25_results, k)
        else:
            return self._alpha_fusion(dense_results, bm25_results, k)
```

`retrieve()` always fetches $k*2$ candidates from each retriever. If the final output is top-5, each retriever returns top-10. This ensures that a document ranked 6th by dense and 3rd by BM25 still makes it into the fusion pool — it might deserve to be in the final top-5 once scores are combined.

Strategy 1: Alpha-weighted score fusion

The idea is simple: normalise both score sets to [0, 1], then take a weighted average.

```

def _alpha_fusion(self, dense_results, bm25_results, k):
    dense_map = {r["chunk_id"]: r["score"] for r in dense_results}
    bm25_map = {r["chunk_id"]: r["score"] for r in bm25_results}

    all_ids = set(dense_map) | set(bm25_map)

    # Min-max normalise dense scores
    d_vals = list(dense_map.values())
    d_min, d_max = min(d_vals), max(d_vals)

    # Min-max normalise BM25 scores
    b_vals = list(bm25_map.values())
    b_min, b_max = min(b_vals), max(b_vals)

    def norm_dense(s):
        return (s - d_min) / max(d_max - d_min, 1e-10)

    def norm_bm25(s):
        return (s - b_min) / max(b_max - b_min, 1e-10)

    fused = []
    for cid in all_ids:
        chunk = dict(all_chunks[cid])
        d_score = norm_dense(dense_map.get(cid, d_min))
        b_score = norm_bm25(bm25_map.get(cid, b_min))
        chunk["score"] = self.alpha * d_score + (1 - self.alpha) * b_score
        chunk["retriever"] = "hybrid"
        fused.append((chunk["score"], chunk))

    fused.sort(key=lambda x: x[0], reverse=True)
    return [c for _, c in fused[:k]]

```

Step by step:

1. Build a `chunk_id → score` lookup for each retriever's results
2. Take the **union** of all candidate IDs (a document only in BM25 is still a candidate)
3. Min-max normalise each score set independently so both live in `[0, 1]`
4. For each candidate, compute `alpha × dense_norm + (1-alpha) × bm25_norm`
5. A document that only appeared in one retriever gets score `0` for the other (mapped to the minimum)
6. Sort by fused score and return top-k

With `alpha=0.7`, the final score is "70% semantic similarity, 30% BM25 keyword match".

Why alpha=0.7?

The alpha value was determined by ablation — running the full 20-query evaluation at several values and recording MRR:

Alpha	MRR
0.3 (BM25-heavy)	0.271
0.5 (equal weight)	0.289
0.7 (dense-heavy)	0.308
0.9 (almost dense)	0.301

MRR peaks around `alpha=0.7`. This reflects the corpus: with 600 recent ML paper abstracts, semantic similarity carries more signal than keyword overlap for most queries. The 30% BM25 contribution helps with exact-term queries without overwhelming the semantic component.

Strategy 2: Reciprocal Rank Fusion (RRF)

RRF is a rank-based fusion method. It ignores raw scores entirely and only uses each document's position in each retriever's sorted list.

```
def _rrf_fusion(self, dense_results, bm25_results, k):
    scores: dict[str, float] = {}
    all_chunks: dict[str, dict] = {}

    for results in [dense_results, bm25_results]:
        for rank, chunk in enumerate(results):
            cid = chunk["chunk_id"]
            scores[cid] = scores.get(cid, 0.0) + 1.0 / (self.rrf_k + rank + 1)
            all_chunks[cid] = chunk

    ranked = sorted(scores.items(), key=lambda x: x[1], reverse=True)[:k]
    result = []
    for cid, score in ranked:
        chunk = dict(all_chunks[cid])
        chunk["score"] = score
        chunk["retriever"] = "hybrid-rrf"
        result.append(chunk)
    return result
```

Step by step:

1. For each retriever's result list, iterate through `(rank, chunk)` pairs
2. Add `1 / (60 + rank + 1)` to that document's running RRF score
3. The constant `60` (from the original RRF paper, Cormack et al. 2009) controls how steeply the contribution falls off with rank

4. A document ranked 1st contributes $1/61 \approx 0.016$; ranked 10th contributes $1/71 \approx 0.014$; ranked 100th contributes $1/161 \approx 0.006$

5. Documents appearing in both lists get contributions from both — their scores sum

The appeal of RRF is that it sidesteps score normalisation entirely. You never need to worry about the fact that BM25 scores are raw values in $[0, \infty)$ while dense scores are cosine similarities in $[0, 1]$.

The surprising result: RRF did not win

Strategy	Recall@5	MRR
Dense baseline	0.250	0.299
BM25 improved	0.367	0.441
Hybrid alpha=0.7	0.267	0.308
Hybrid RRF	0.267	0.287

RRF scored lower than both BM25 alone and alpha fusion. This is counter-intuitive — RRF is theoretically more robust than score-level fusion. Why didn't it win?

The answer lies in what RRF throws away. Alpha fusion, after min-max normalisation, preserves score *magnitude*. A dense score of 0.95 vs 0.60 tells you the first document is far more similar — and that information survives into the fused score. RRF collapses those two documents into ranks 1 and 2, treating the gap between them as $1/61 - 1/62 \approx 0.0003$. On a corpus where dense embeddings carry strong signal (well-represented ML terminology), discarding magnitude hurts.

When RRF wins

RRF is the right choice when retriever score scales are incomparable or unstable — for example, when fusing results from different embedding models, different corpora, or sparse retrievers with very different vocabulary sizes. For two retrievers that are both well-calibrated on the same corpus, alpha fusion with good normalisation can outperform it.

The practical takeaway: **test both** on your corpus. The answer depends on how well-calibrated your retrievers are, not on the theory.

Cross-Encoder Reranking

Retrieval gives us a ranked list of candidates. Reranking asks: given the query *and* a specific document together, how relevant is this document really? That joint question is something a retriever — which scores query and documents independently — cannot answer well.

This page explains the two-stage retrieve-then-rerank architecture, walks through the `Reranker` class in `src/retriever.py`, and covers the latency tradeoff that makes this pattern practical.

Why retrieval alone isn't enough

When `DenseRetriever` embeds a query, it produces one vector. Each document was already embedded at index time into its own vector. Relevance is approximated by the cosine distance between those two independently-produced vectors.

The problem: the encoding happens in isolation. The query encoder never sees the document; the document encoder never sees the query. They're strangers who never met.

A **cross-encoder** does the opposite: it encodes the query and document *together*, concatenated as a single input sequence. Every attention head in every layer can attend to both the query tokens and the document tokens simultaneously. The result is a single relevance score that captures fine-grained query-document interactions that independent encoding misses.

```
Bi-encoder (retrieval):
  query → encoder → q_vec ↗
                             |— cosine_sim → score
  doc   → encoder → d_vec ↘

Cross-encoder (reranking):
  [query] [SEP] [document] → encoder → relevance score
```

The catch: you cannot pre-compute cross-encoder scores. Every query requires a fresh forward pass over every candidate. For 600,000 documents that's prohibitive; for 20 candidates, it runs in under a second.

This is the two-stage strategy: retrieve fast over the full corpus, then rerank the short candidate list accurately.

The Reranker class

```

class Reranker:
    def __init__(
        self,
        model_name: str = "cross-encoder/ms-marco-MiniLM-L-6-v2",
    ) -> None:
        logger.info(f"Loading cross-encoder: {model_name}")
        self.model = CrossEncoder(model_name)

    def rerank(
        self,
        query: str,
        candidates: list[dict],
        top_k: int = 5,
    ) -> list[dict]:
        if not candidates:
            return []

        # Build (query, passage) pairs for the cross-encoder
        pairs = [(query, c["text"]) for c in candidates]
        scores = self.model.predict(pairs)

        # Zip scores back to chunks and sort descending
        scored = sorted(
            zip(scores, candidates),
            key=lambda x: x[0],
            reverse=True,
        )

        results = []
        for score, chunk in scored[:top_k]:
            chunk = dict(chunk)
            chunk["score"] = float(score)
            chunk["retriever"] = "reranked"
            results.append(chunk)

        return results

```

The key line is `self.model.predict(pairs)`. `CrossEncoder.predict()` from `sentence-transformers` accepts a list of (query, passage) tuples and returns a numpy array of logits — one per pair — in a single batched forward pass. This is faster than calling `predict()` 20 times individually because the model processes them as a batch on the same device.

Why k=20 candidates, not k=5?

In the notebook, `HybridRetriever.retrieve()` is called with `k=20` before reranking, not `k=5`. This is deliberate.

The reranker fixes rank order within the candidate set — but it can't promote a document that wasn't retrieved in the first place. If the correct paper is ranked 7th by hybrid retrieval and you only pass top-5 to the reranker, that paper is gone.

Fetching `k=20` for reranking and returning `top_k=5` means:

- Retrieval casts a wide net (Recall@20 is higher than Recall@5)
- Reranking sharpens the final top-5 from that wider pool

The tradeoff is latency: 20 cross-encoder pairs instead of 5. On CPU with the MiniLM model, 20 pairs takes roughly 80–120ms. That's acceptable for interactive use.

The ms-marco-MiniLM-L-6-v2 model

The default model is `cross-encoder/ms-marco-MiniLM-L-6-v2` from Hugging Face.

MS MARCO (Microsoft Machine Reading Comprehension) is a large-scale dataset of real Bing search queries paired with passages and human-judged relevance labels. A model trained on MS MARCO learns what "relevant passage for a query" means from millions of real web search examples.

MiniLM-L-6 means a distilled BERT-style transformer with 6 layers and 22MB on disk. It's fast enough to run on CPU without a GPU (the primary reason it was chosen for this tutorial — no VRAM is consumed during reranking, leaving GPU memory free for the LLM).

Zero-shot transfer to ArXiv

The model was trained on web search passages, not academic paper abstracts. It is applied here zero-shot — with no fine-tuning on the ArXiv corpus. Despite this domain gap, it still improves MRR from 0.287 to 0.363 on the RRF+Rerank configuration. Fine-tuning on in-domain data (query-abstract pairs from ArXiv) would likely improve this further.

Latency profile

Measured on a single CPU core (Intel Core i7), 20 candidate pairs:

Step	Latency
Dense retrieval (FAISS, 600 papers)	~5ms
BM25 scoring (rank_bm25, 600 papers)	~8ms
Hybrid fusion	<1ms
Cross-encoder reranking (20 pairs, CPU)	~90–120ms
Total pipeline	~120ms

Most of the latency is in reranking. For a chatbot-style interface where the user waits for an LLM response anyway, 120ms is imperceptible. For batch evaluation over 20 queries, it adds a few seconds.

Impact on the benchmark

Strategy	Recall@5	MRR
Hybrid RRF	0.267	0.287
Hybrid RRF + Rerank	0.333	0.363

Reranking adds +0.066 Recall@5 and +0.075 MRR over RRF alone. The reranker rescues documents that were scored too conservatively by rank-based fusion — their cross-encoder score promotes them into the final top-5.

The reranker does not recover all of RRF's gap versus BM25 alone (MRR 0.363 vs 0.441 for BM25 improved), which is why Part 2's headline result is "improved BM25 tokenisation" rather than reranking. But the reranker adds consistent, predictable improvement on top of any upstream retrieval strategy, making it a low-risk addition to any pipeline.

Evaluation

Measuring retrieval quality is harder than it looks. The naive approach — pick 5 queries, eyeball the results, call it good — is almost always misleading. This page explains how the 20-query benchmark is set up, why we replaced an earlier 5-query version, and how the `compute_retrieval_metrics()` function works.

Why evaluation is easy to get wrong

There are two common failure modes in RAG evaluation:

Too few queries. With 5 queries, random variation dominates the signal. A system with MRR 0.667 on 5 queries might have MRR 0.350 on 50 queries. The small set happened to contain queries that this system handles well.

Hand-picked queries. If you design test queries after looking at the system's outputs (even informally), you've contaminated the benchmark. Queries that "feel like they should work" will work for any reasonable retrieval system.

This project ran into exactly the first problem. The original 5-query benchmark produced results like this:

Strategy	Recall@5	MRR
Dense	0.533	0.417
BM25 (original tokenisation)	0.533	0.667
Hybrid alpha=0.7	0.533	0.417
Hybrid RRF + Rerank	0.467	0.500

These numbers look reasonable, but they're noisy. When the benchmark was expanded to 20 queries — same methodology, same corpus — results dropped significantly across all strategies and the relative ranking of methods changed.

Lower numbers on a harder benchmark are more informative

The 5-query BM25 result (MRR 0.667) looked impressive. The 20-query result (MRR 0.441 with improved tokenisation, 0.333 with original) is the honest one. Reporting the inflated number would have suggested the system is better than it is.

The 20-query benchmark

The benchmark is defined as a list of `(query, relevant_chunk_ids)` pairs. Relevant chunk IDs are manually identified by checking which chunks in the corpus actually answer each query.

The 20 queries were designed to cover different retrieval difficulty levels:

- **Exact-term queries** — "BM25 information retrieval scoring" (BM25 should win)
- **Semantic queries** — "how do language models handle long documents" (dense should win)
- **Multi-aspect queries** — "efficient training of large language models" (multiple relevant papers)
- **Rare-term queries** — specific model or dataset names from recent papers

Queries were written before inspecting the retrieval results to avoid contamination. The relevant chunk IDs were then identified by searching the corpus manually.

The metrics

Three metrics are computed per strategy:

Recall@5 — what fraction of relevant documents appear in the top-5?

```
Recall@5 = |relevant n top_5| / |relevant|
```

If a query has 3 relevant chunks and 2 appear in top-5, $\text{Recall@5} = \frac{2}{3} \approx 0.667$.

Precision@5 — what fraction of the top-5 are relevant?

```
Precision@5 = |relevant n top_5| / 5
```

If 2 out of 5 retrieved chunks are relevant, $\text{Precision@5} = 0.4$.

MRR (Mean Reciprocal Rank) — what is the reciprocal rank of the *first* relevant document, averaged over all queries?

```
RR(query) = 1 / rank_of_first_relevant  
MRR = mean(RR) over all queries
```

MRR = 1.0 means the top result is always relevant. MRR = 0.5 means the first relevant result is at rank 2 on average. MRR = 0.299 (the dense baseline) means the first relevant result is near rank 3–4.

MRR is the primary metric because it measures what users experience: how far down the list do they need to scroll before seeing something useful?

```
compute_retrieval_metrics()
```

The function is defined in notebook 02 (not in `src/`) since it's evaluation scaffolding rather than production code:

```
def compute_retrieval_metrics(
    retriever,
    eval_set: list[tuple[str, list[str]]],
    k: int = 5,
) -> dict:
    recalls, precisions, rr_scores = [], [], []

    for query, relevant_ids in eval_set:
        results = retriever.retrieve(query, k=k)
        retrieved_ids = [r["chunk_id"] for r in results]

        relevant_set = set(relevant_ids)
        hits = [rid for rid in retrieved_ids if rid in relevant_set]

        recall = len(hits) / len(relevant_set) if relevant_set else 0.0
        precision = len(hits) / k

        # MRR: find rank of first hit
        rr = 0.0
        for rank, rid in enumerate(retrieved_ids, start=1):
            if rid in relevant_set:
                rr = 1.0 / rank
                break

        recalls.append(recall)
        precisions.append(precision)
        rr_scores.append(rr)

    return {
        "recall@k": round(sum(recalls) / len(recalls), 3),
        "precision@k": round(sum(precisions) / len(precisions), 3),
        "mrr": round(sum(rr_scores) / len(rr_scores), 3),
    }
```

Running this function against each retriever strategy on the same 20-query set produces a directly comparable table, because the only variable is the retriever.

Running the evaluation

In notebook 02, the evaluation loop looks like this:

```
strategies = {
    "Dense": dense_retriever,
    "BM25 improved": bm25_retriever,
    "Hybrid alpha=0.7": hybrid_alpha,
    "Hybrid RRF": hybrid_rrf,
    "Hybrid RRF + Rerank": rerank_pipeline, # wraps retrieve(k=20) + rerank(top_k=5)
}

results = {}
for name, retriever in strategies.items():
    results[name] = compute_retrieval_metrics(retriever, EVAL_SET, k=5)
    print(f"{name:30s} {results[name]}")
```

Each strategy gets exactly the same 20 queries and the same relevant-ID ground truth. The output is the table shown in the [Results and Limits](#) page.

Results and Limits

This page collects the full results from both evaluation rounds, interprets the key findings, explains what the numbers mean for practical use, and identifies what Part 2 still cannot fix — setting up the motivation for Part 3.

Full results table

5-query evaluation (original benchmark — for comparison only)

Strategy	Recall@5	MRR
Dense baseline	0.533	0.417
BM25 (original tokenisation)	0.533	0.667
Hybrid alpha=0.7	0.533	0.417
Hybrid RRF + Rerank	0.467	0.500

20-query evaluation (current benchmark — the honest numbers)

Strategy	Recall@5	Precision@5	MRR
Dense baseline	0.250	0.120	0.299
BM25 improved tokenisation	0.367	0.190	0.441
Hybrid alpha=0.7	0.267	0.130	0.308
Hybrid RRF	0.267	0.130	0.287
Hybrid RRF + Rerank	0.333	0.170	0.363

The 5-query numbers are preserved for transparency, not because they're trustworthy. Every number below compares against the 20-query benchmark.

Key findings

Finding 1: BM25 tokenisation was the biggest lever

The single most impactful change was switching from `text.lower().split()` to the `_tokenise()` function — lowercase, strip punctuation, remove stop words. This lifted BM25 MRR from approximately 0.333 (with the original whitespace split) to 0.441, a gain of roughly +0.108.

Why did this matter so much? ML paper abstracts are dense with exact technical terms. "LoRA", "RLHF", and "attention mechanism" are the signals that differentiate relevant from irrelevant. Under the original tokeniser, "attention." (end of sentence) and "attention" (mid-sentence) were different tokens, causing a term-frequency mismatch that quietly deflated BM25 scores across the board. Fixing this freed BM25 to do what it was designed for.

Finding 2: Hybrid search did not beat BM25 alone

This is the most surprising result in Part 2. Every intuition about hybrid retrieval says it should outperform either component on its own — and in the literature, it usually does. But on this 20-query benchmark:

Strategy	MRR
BM25 improved	0.441
Hybrid alpha=0.7	0.308
Hybrid RRF	0.287

Adding dense scores to the mix *hurt* performance.

The most likely explanation: with improved BM25 tokenisation, keyword search became very good on this corpus. The queries in the benchmark skew toward exact technical terms (model names, method names, benchmark names) — the kind of queries where BM25 dominates. Adding dense scores at alpha=0.3 introduced noise for these queries without compensating on the paraphrase queries where dense would help.

This is a corpus-composition effect, not a general finding about hybrid retrieval. A benchmark with more semantic / paraphrase queries would likely reverse this result.

What this means for your own RAG system

Don't assume hybrid retrieval beats its components. Always measure on your actual query distribution. If your users ask exact-term questions (e.g., product names, SKU codes, error messages), a well-tuned BM25 may be better than any hybrid.

Finding 3: Reranking adds consistent gain over any upstream retriever

The cross-encoder reranker improved MRR by +0.075 over Hybrid RRF (0.287 → 0.363). This is a consistent pattern: the reranker doesn't care which retriever produced the candidates, it just re-scores the top-20 with better query-document interaction.

This makes reranking a low-risk addition to any pipeline. You're not replacing retrieval — you're adding a second pass that can only improve rank order within the candidate set you already have.

Finding 4: The 5-query numbers were misleading

The original BM25 MRR of 0.667 on 5 queries dropped to approximately 0.333 on 20 queries (before tokenisation improvements). That's not a system getting worse — it's noise in a small benchmark getting resolved. The 5-query evaluation happened to contain queries that BM25 handled unusually well. The 20-query benchmark has harder queries and a more realistic distribution.

What Part 2 does not fix

Single-hop retrieval

Every retrieval strategy in Part 2 runs exactly one search and returns a fixed top-k. If the right answer requires synthesising information from two different papers — one about LoRA architecture and another about quantisation efficiency — a single retrieval pass may not surface both.

Multi-hop retrieval requires iterative querying: retrieve once, read the results, formulate a follow-up query based on what's missing, retrieve again. Part 3 implements this as part of the LangGraph agent.

Silent retrieval failure

When retrieval fails (the right paper is not in the top-5), the system proceeds to generation anyway. The LLM generates a plausible-sounding answer from whatever was retrieved, with no indication that the retrieved context was poor. There is no mechanism to detect "I found nothing useful" vs "I found exactly what was asked for".

No hallucination detection

The generation stage in Part 2 is identical to Part 1: inject the top-5 chunks into a prompt, generate, return. The system does not verify whether the LLM's answer is actually supported by the retrieved chunks. An LLM that "knows" the answer from training data may generate a confident response that has nothing to do with the retrieved context.

What Part 3 adds

Part 3 wraps the Advanced RAG retrieval pipeline in a LangGraph state machine that addresses both remaining failure modes:

1. **Document grading** — after retrieval, the LLM grades each chunk: "Is this document relevant to the query?"
Chunks that fail grading are filtered out.
2. **Web search fallback** — if too few chunks pass grading, the agent triggers a web search (Tavily) to supplement the corpus.
3. **Answer faithfulness grading** — after generation, the LLM checks whether each claim in the answer is supported by the retrieved context. If not, the answer is flagged as a hallucination.
4. **Retry loop** — on a hallucination flag, the agent regenerates (up to twice) before returning.

This is the CRAG (Corrective RAG) architecture. Legacy small-scope runs showed high faithfulness with little fallback, while current 4,000-baseline runs expose harder query conditions (see `artifacts/eval_results/03_agentic_rag_4000.json` for current agentic baseline behavior).

Continue to [Part 3 — Agentic RAG](#).

6 Part 3 — Agentic RAG

Part 3 — Agentic RAG: Overview

Parts 1 and 2 built pipelines: a question comes in, fixed steps execute in order, an answer comes out. There is no feedback, no reconsideration, and no fallback when the retriever returns weak results. The pipeline cannot tell the difference between a great answer and a hallucinated one.

Part 3 changes this. Instead of a pipeline, we build a **reasoning loop** — a graph of nodes where the LLM actively decides what happens next.

What Part 3 adds

Three capabilities that no pipeline can provide:

Relevance gating. After retrieval, an LLM judge reads each retrieved document and decides whether it actually answers the question. If the corpus produces nothing useful, the agent takes a different path instead of generating a bad answer from bad evidence.

Web search fallback. When the local corpus is genuinely insufficient, the agent queries DuckDuckGo and appends real web results to the context. Corpus gaps do not mean a dead end.

Self-correction. After generating an answer, a second LLM judge checks whether the answer makes claims not supported by the retrieved context. If the answer hallucinates, the agent loops back and tries again — up to two times.

The agentic loop concept

Think of the Part 2 pipeline as a single train journey: you board at retrieve, stop at rerank, and get off at generate. There is only one route.

An agent is more like a sat-nav: it starts at retrieve, checks whether the result is useful, and then *decides* whether to take the generate route or the web-search detour. After generating, it checks the answer and either ends the journey or loops back. The route through the graph is determined at runtime, not at design time.

This is what "agentic" means: the system has agency over its own execution path.

Full graph diagram

Five nodes. Two conditional routing decisions. One state object that flows through all of them and accumulates the evidence, grades, and trace as it goes.

Results preview: Part 3 vs Part 2

Part 2 measures retrieval quality — how good is the ranked list. Part 3 measures something different: agent behaviour over full question-answering.

Metric	Part 2 (pipeline)	Part 3 (agent)
Relevant docs retrieved	—	10 / 10 (100%)
Web search triggered	—	0 / 10 (0%)
Faithful answers	—	7 / 10 (70%)
Average latency	~200 ms	~15 s / query

The latency increase is real and significant. Every query now involves multiple LLM calls for grading, not just one for generation. This is the core tradeoff of agentic RAG: higher quality at higher cost.

Why 10 queries, not 20?

Each query takes ~15 seconds because of multiple sequential LLM calls. 20 queries would take ~5 minutes. 10 is a reasonable evaluation budget for a tutorial notebook. The tradeoff between coverage and latency is discussed further in [Evaluation](#).

The CRAG paper

This architecture implements Corrective Retrieval-Augmented Generation (CRAG), proposed by Yan et al. (2024). The core idea from the paper is that retrieval is not always correct, and the system should detect and correct retrieval failures before generating.

We implement the spirit of CRAG — retrieval grading, web fallback, faithfulness checking — with adaptations for our fully local stack. The [CRAG Architecture](#) page explains the mapping in detail.

The notebook file

`notebooks/03_agentic_rag_langgraph.ipynb` is the runnable version of this section. It depends on the FAISS index built in notebook 01. Each cell maps to one node in the graph, so you can test nodes in isolation before assembling the full agent.

Run notebook 01 first

Notebook 03 calls `load_index_and_chunks()` and expects `artifacts/faiss_index/` to exist. Build it by running notebook 01 if you have not already.

What's next

[LangGraph Basics](#) introduces the framework we use to build the graph: what a `StateGraph` is, how nodes and edges work, and the key API calls — before any RAG-specific code appears.

LangGraph Basics

Before building the RAG agent, we need to understand the framework it runs on. LangGraph is a library for building stateful, multi-step applications where a language model controls the execution flow. This page explains the core abstractions with simple examples, then shows how they map to our RAG code.

What LangGraph is

LangGraph models your application as a **directed graph**. Each node in the graph is a Python function that reads a shared state, does some work, and returns updates to that state. Edges connect nodes, and conditional edges let the runtime choose which node to visit next based on the current state.

This sounds abstract. Here is the simplest possible graph — one that just echoes a message:

```
from langgraph.graph import StateGraph, END
from typing import TypedDict

class SimpleState(TypedDict):
    message: str
    processed: bool

def process(state: SimpleState) -> dict:
    return {"processed": True}

builder = StateGraph(SimpleState)
builder.add_node("process", process)
builder.set_entry_point("process")
builder.add_edge("process", END)

graph = builder.compile()
result = graph.invoke({"message": "hello", "processed": False})
# result = {"message": "hello", "processed": True}
```

Four steps every graph needs:

1. **Define state** — a `TypedDict` that all nodes share.
2. **Add nodes** — Python functions that accept and return state dictionaries.
3. **Set entry point** — which node runs first.
4. **Add edges** — how control flows between nodes.

StateGraph vs a regular pipeline

A regular pipeline is a list of function calls in a fixed order:

```
docs = retrieve(question)
ranked = rerank(docs)
answer = generate(question, ranked)
```

A `StateGraph` stores all intermediate values in a shared state object and routes between nodes dynamically. The same question might take a different path through the graph depending on what `grade_documents` returns.

The key difference: **the path through the graph is not fixed at write time.**

TypedDict state

Every `LangGraph` graph is parameterised by a state type. Use a `TypedDict` (not a dataclass or Pydantic model) — `LangGraph` merges partial dict updates from each node into the shared state automatically.

```
from typing import TypedDict, Optional

class GraphState(TypedDict):
    question: str          # never changes after initialisation
    documents: list[dict]   # set by retrieve
    answer: str             # set by generate
    grade: str              # set by grade - "relevant" or "irrelevant"
```

Each node receives the full current state and returns only the keys it wants to update:

```
def retrieve(state: GraphState) -> dict:
    docs = retriever.search(state["question"])
    return {"documents": docs}  # only updates "documents"
```

`LangGraph` merges this return value into the existing state. Keys not returned are unchanged. This makes nodes composable — each one only knows about the fields it needs.

add_node, add_edge, add_conditional_edges

`add_node(name, function)` registers a node. The function signature must be `(state: YourState) -> dict`.

`add_edge(from_node, to_node)` adds a fixed edge — after `from_node` always run `to_node`. Use `END` as the target to terminate the graph.

`add_conditional_edges(from_node, routing_function, edge_map)` is the key to agentic behaviour. The routing function receives the current state and returns a string key. The edge map translates that key to the next node:

```
def route_after_grading(state: GraphState) -> str:
    return state["grade"] # "relevant" or "irrelevant"

builder.add_conditional_edges(
    "grade_documents",
    route_after_grading,
    {
        "relevant": "generate_answer",
        "irrelevant": "web_search",
    }
)
```

After `grade_documents` runs, `LangGraph` calls `route_after_grading`, reads the returned string, looks it up in the edge map, and runs the corresponding node next.

compile() and invoke()

`builder.compile()` validates the graph, checks for unreachable nodes and missing edges, and returns a compiled `CompiledGraph` object.

`graph.invoke(initial_state)` runs the graph synchronously from the entry point to `END`, returning the final state dictionary.

```
rag_agent = graph_builder.compile()

result = rag_agent.invoke({
    "question": "What is RLHF?",
    "documents": [],
    "filtered_documents": [],
    "retrieval_grade": "",
    "generation": "",
    "generation_attempts": 0,
    "faithfulness_grade": "",
    "execution_trace": [],
})

print(result["generation"])
```

The .graph attribute gotcha

In LangGraph 0.4.x the compiled graph does **not** have a `.graph` attribute. If you try `rag_agent.graph.nodes.keys()` you will get an `AttributeError`. To inspect the graph structure, use `graph_builder.nodes.keys()` on the **builder** object before compiling, not on the compiled result.

```
# Correct - inspect the builder
print(list(graph_builder.nodes.keys()))
# ['retrieve', 'grade_documents', 'web_search', 'generate_answer', 'grade_hallucination']

# Wrong - compiled graph has no .graph attribute in 0.4.x
# rag_agent.graph.nodes.keys() # AttributeError
```

Putting it together

Here is the complete graph construction for our RAG agent, without the node implementations (those are covered in subsequent pages):

```
from langgraph.graph import StateGraph, END

graph_builder = StateGraph(GraphState)

# Register the five nodes
graph_builder.add_node("retrieve", retrieve)
graph_builder.add_node("grade_documents", grade_documents)
graph_builder.add_node("web_search", web_search)
graph_builder.add_node("generate_answer", generate_answer)
graph_builder.add_node("grade_hallucination", grade_hallucination)

# Fixed edges
graph_builder.set_entry_point("retrieve")
graph_builder.add_edge("retrieve", "grade_documents")
graph_builder.add_edge("web_search", "generate_answer")
graph_builder.add_edge("generate_answer", "grade_hallucination")

# Conditional edges
graph_builder.add_conditional_edges(
    "grade_documents",
    route_after_grading,
    {"relevant": "generate_answer", "irrelevant": "web_search"}
)
graph_builder.add_conditional_edges(
    "grade_hallucination",
    route_after_faithfulness,
    {"faithful": END, "hallucinated": "generate_answer"}
)

rag_agent = graph_builder.compile()
```

Twenty-five lines to define a self-correcting, web-augmented research agent. The next page explains the state type and the architectural paper behind it.

CRAG Architecture

This page explains the research paper behind the agent design, maps our implementation to the paper, and documents the `GraphState TypedDict` — the shared memory that every node reads from and writes to.

The CRAG paper

Corrective Retrieval-Augmented Generation (Yan et al., 2024) diagnoses a fundamental problem with standard RAG: the retriever is not always right, and the generator does not know when it is not.

In a standard RAG pipeline, whatever the retriever returns goes directly into the prompt. If the top-5 chunks are tangentially related or outright wrong for the query, the LLM generates an answer anyway — and it often sounds confident. The pipeline has no mechanism to detect retrieval failure before generation.

CRAG's solution has three stages:

- 1. **Evaluate retrieval quality.** A lightweight evaluator (in the paper, a fine-tuned T5; in our implementation, an LLM judge) scores each retrieved document against the query. Documents are classified as correct, incorrect, or ambiguous.
- 2. **Take corrective action based on the score.** If at least one document scores "correct", proceed to generation. If the retrieval is ambiguous or entirely incorrect, fall back to a web search to supplement or replace the corpus results.
- 3. **Generate from quality-controlled context.** Generation only happens after the context has passed through the evaluator gate. Bad evidence cannot reach the LLM.

Our implementation adds a fourth stage not in the original paper: a post-generation faithfulness check that loops back if the answer introduces unsupported claims.

Our implementation vs the paper

CRAG (Yan et al.)	Our implementation
Fine-tuned T5 relevance scorer	granite4.1:8b with a JSON prompt
3-way classification: correct / incorrect / ambiguous	2-way: relevant / irrelevant (see Threshold Improvement)
Web search to supplement ambiguous results	Web search only on fully irrelevant results

CRAG (Yan et al.)	Our implementation
No post-generation check	grade_hallucination node with retry loop
Cloud LLM for generation	Local granite4.1:8b via Ollama

The most important difference is the evaluator. The paper's T5 scorer is fast and trained specifically for document relevance. Our LLM judge is slower but requires no fine-tuning, which keeps the entire system local and zero-cost to deploy.

The GraphState TypedDict

All five nodes communicate through a single `TypedDict`. Every node receives the complete state and returns only the keys it modifies.

```
from typing import TypedDict, Optional

class GraphState(TypedDict):
    question: str
    documents: list[dict]
    filtered_documents: list[dict]
    retrieval_grade: str
    generation: str
    generation_attempts: int
    faithfulness_grade: str
    execution_trace: list[str]
```

Field-by-field explanation

question: str The user's query. Set once at invocation and never modified. Every node that needs the question reads it from here rather than being passed it as a parameter — there is only one place the question lives.

documents: list[dict] The raw retrieved documents from the `retrieve` node. Each dict has at minimum a `"content"` key with the chunk text. This is the unfiltered output of the `DenseRetriever`.

filtered_documents: list[dict] The documents that survive grading. After `grade_documents` runs, this contains only the chunks that the LLM judge rated as relevant. If `web_search` runs, its results are appended here too. This is what `generate_answer` uses as context — never `documents` directly.

retrieval_grade: str Either `"relevant"` or `"irrelevant"`. Set by `grade_documents` and read by the conditional edge routing function. This is the single value that determines whether the agent goes to `generate_answer` or `web_search` next.

generation: str The LLM's generated answer. Set by `generate_answer`. On a hallucination-triggered retry, it gets overwritten with the new attempt.

generation_attempts: int A counter incremented by `generate_answer` each time it runs. The `grade_hallucination` routing function checks this to enforce the two-attempt maximum — without it, a persistently hallucinating LLM could loop forever.

faithfulness_grade: str Either "faithful" or "hallucinated". Set by `grade_hallucination` and read by its conditional edge. Determines whether the graph terminates or loops back.

execution_trace: list[str] A list of strings that each node appends to, recording what it did and why. This is purely for debugging — it has no effect on routing. After a query completes, you can inspect `result["execution_trace"]` to see the complete step-by-step log of what the agent decided and why.

The execution_trace in practice

Debugging a graph without a trace is painful. You can see the final answer but not why the agent took the path it did. The trace makes every decision visible:

```
result = rag_agent.invoke(initial_state)

for step in result["execution_trace"]:
    print(step)
```

Example output for a query that passes through the happy path:

```
retrieve: found 10 documents for 'attention mechanisms in transformers'
grade_documents: doc 0 → relevant (score: high match on attention mechanism description)
grade_documents: doc 1 → relevant (score: mentions self-attention and query-key-value)
grade_documents: doc 2 → irrelevant (score: about image classification, not attention)
...
grade_documents: 4 relevant out of 10, grade=relevant
generate_answer: attempt 1
grade_hallucination: 0 unsupported claims → faithful
```

And for a query that triggers the web fallback and then a retry:

```
retrieve: found 10 documents for 'LLM watermarking 2024'
grade_documents: 0 relevant out of 10, grade=irrelevant
web_search: querying DuckDuckGo for 'LLM watermarking 2024'
web_search: appended 3 web results to filtered_documents
generate_answer: attempt 1
grade_hallucination: 2 unsupported claims → hallucinated
generate_answer: attempt 2
grade_hallucination: 0 unsupported claims → faithful
```

The trace turns an opaque black box into a legible audit trail.

What's next

[LLM as Judge](#) goes inside the two grading nodes — the exact prompts used, how JSON output is parsed, and why granite4.1:8b was chosen as the judge model.

LLM as Judge

Two nodes in the graph make binary decisions using a language model: `grade_documents` decides whether retrieved chunks are relevant, and `grade_hallucination` decides whether the generated answer is faithful to the context. This page explains both nodes in detail — the prompts, the parsing logic, and why reliable JSON output matters.

Why use an LLM as a judge?

The alternative to an LLM judge is a heuristic: score by cosine similarity, count keyword overlap, or use a fine-tuned classifier. These approaches can work, but they have a ceiling. A chunk that scores 0.88 cosine similarity might still be about the wrong subtopic. An LLM can read the chunk and the question together and make a semantic judgment that a vector score cannot.

The tradeoff is speed. Each LLM call takes 1–3 seconds. With 10 retrieved documents, `grade_documents` makes 10 LLM calls per query. This is the primary driver of the ~15s average latency in Part 3.

The `grade_documents` node

This node iterates over every document in `state["documents"]`, asks the LLM whether the document is relevant to the question, counts the relevant ones, and sets `retrieval_grade`.

```
GRADING_PROMPT = """You are a relevance grader. Given a user question and a document,
assess whether the document contains information relevant to answering the question.
```

```
Question: {question}
```

```
Document: {document}
```

```
Respond with ONLY valid JSON in this exact format:
```

```
{
  "score": "yes" or "no",
  "reasoning": "one sentence explaining your decision"
}
```

```
def grade_documents(state: GraphState) -> dict:
    question = state["question"]
    documents = state["documents"]
    filtered_documents = []
    n_relevant = 0
    trace = list(state["execution_trace"])

    for doc in documents:
        prompt = GRADING_PROMPT.format(
            question=question,
            document=doc["content"][:800] # truncate long chunks
        )
        response = ollama.chat(
            model="granite4.1:8b",
            messages=[{"role": "user", "content": prompt}]
        )
        try:
            result = json.loads(response["message"]["content"])
            if result.get("score") == "yes":
                filtered_documents.append(doc)
                n_relevant += 1
                trace.append(f"grade_documents: doc → relevant")
            else:
                trace.append(f"grade_documents: doc → irrelevant")
        except json.JSONDecodeError:
            # If parsing fails, treat as irrelevant - fail safe
            trace.append(f"grade_documents: doc → irrelevant (parse error)")

    retrieval_grade = "relevant" if n_relevant >= 1 else "irrelevant"
    trace.append(
        f"grade_documents: {n_relevant} relevant out of {len(documents)}, "
        f"grade={retrieval_grade}"
    )

    return {
        "filtered_documents": filtered_documents,
        "retrieval_grade": retrieval_grade,
        "execution_trace": trace,
    }
```

Line-by-line walkthrough:

- The prompt truncates each chunk to 800 characters. Full chunks can be 512 characters of content, but metadata fields can push the total higher. Truncation prevents the prompt from exceeding the model's context window on pathological chunks.

- `json.loads()` is wrapped in a try/except. If the model returns prose instead of JSON, we fail safe: treat the document as irrelevant rather than crashing.
 - The threshold `n_relevant >= 1` is the 2-tier threshold introduced as Improvement 5. See [Threshold Improvement](#) for the history and the measured impact.
 - Only `filtered_documents` — not `documents` — flows to `generate_answer`. Raw ungraded chunks never reach the generation prompt.
-

The grade_hallucination node

After generation, this node checks whether the answer makes claims that are not supported by the retrieved context. It counts "unsupported claims" — specific assertions in the answer that cannot be traced back to any document in `filtered_documents`.

```
HALLUCINATION_PROMPT = """You are a faithfulness checker. Given an answer and the
source documents used to generate it, identify claims in the answer that are NOT
supported by the documents.
```

```
Source documents:
{context}
```

```
Answer to check:
{answer}
```

```
Respond with ONLY valid JSON in this exact format:
```

```
{{
  "unsupported_claims": <integer count of unsupported claims>,
  "reasoning": "brief explanation"
}}"""
```

```
def grade_hallucination(state: GraphState) -> dict:
    filtered_documents = state["filtered_documents"]
    generation = state["generation"]
    trace = list(state["execution_trace"])

    context = "\n\n".join(
        doc["content"] for doc in filtered_documents
    )

    prompt = HALLUCINATION_PROMPT.format(
        context=context[:3000], # cap context length
        answer=generation
    )

    response = ollama.chat(
        model="granite4.1:8b",
        messages=[{"role": "user", "content": prompt}]
    )

    try:
        result = json.loads(response["message"]["content"])
        unsupported = int(result.get("unsupported_claims", 0))
    except (json.JSONDecodeError, ValueError):
        unsupported = 0 # fail safe: assume faithful if parse fails

    faithfulness_grade = "faithful" if unsupported == 0 else "hallucinated"
    trace.append(
        f"grade_hallucination: {unsupported} unsupported claims "
        f"→ {faithfulness_grade}"
    )

    return {
        "faithfulness_grade": faithfulness_grade,
        "execution_trace": trace,
    }
```

Key decisions:

- The context is capped at 3000 characters. With up to 10 filtered documents, the total context can be large. Capping prevents latency spikes while still giving the judge enough to work with.

- The fail-safe on parse error assumes faithful (returns 0 unsupported claims). This is the correct conservative choice: we should only retry when we are confident the answer hallucinated, not because the judge failed to produce valid JSON.
- `unsupported_claims` is an integer, not a boolean. This is intentional: zero means faithful, any positive number means hallucinated. Future work could use the count to calibrate confidence rather than applying a hard threshold at 1.

Why granite4.1:8b for judging?

Several properties make granite4.1:8b a good judge model for this task:

Reliable JSON. The model follows the JSON format instruction consistently. In testing, parse failures were rare (under 5% of calls). Many smaller models produce well-formed prose but inconsistent JSON, requiring more fragile parsing logic.

Calibrated conservatism. When the document and question are clearly unrelated, the model says "no" confidently. When there is a partial match, it tends toward "no" rather than inflating relevance — which is what you want from a gating mechanism.

Speed. At 8B parameters running locally, inference takes 1–3 seconds per call. A larger model would produce better judgments but would make the ~15s average latency substantially worse.

Improving judge accuracy

The single biggest lever for improving faithfulness from 70% is prompt engineering on the judge prompts. The current prompts are intentionally simple. Techniques like chain-of-thought ("reason step by step before deciding") or few-shot examples with correct labels can push judge accuracy significantly higher without changing the graph architecture.

What's next

[Web Search Fallback](#) covers the `web_search` node — when it fires, how DuckDuckGo results are formatted as documents, and the tradeoffs of injecting uncontrolled web content into the context.

Web Search Fallback

The `web_search` node fires when `grade_documents` finds zero relevant documents in the local corpus. Instead of generating a bad answer from bad evidence, the agent queries the web and appends the results to `filtered_documents` before generation.

When the fallback fires

The conditional edge after `grade_documents` makes a binary choice:

```
def route_after_grading(state: GraphState) -> str:
    return state["retrieval_grade"] # "relevant" or "irrelevant"

graph_builder.add_conditional_edges(
    "grade_documents",
    route_after_grading,
    {
        "relevant": "generate_answer",
        "irrelevant": "web_search",
    }
)
```

`retrieval_grade` is "irrelevant" only when **zero** documents passed the relevance check — not one, not a weak one, but zero. With the 2-tier threshold introduced in Improvement 5, a single relevant document is enough to skip the web search entirely.

In our 10-query evaluation over 600 ArXiv ML/AI papers, `web_search` was triggered **0 out of 10 times** (0%). This is a good outcome: it means the local corpus was sufficient for every query in the evaluation set. The web fallback exists as a safety net for genuine corpus gaps, not as a default behaviour.

The web_search node

```

from duckduckgo_search import DDGS

def web_search(state: GraphState) -> dict:
    question = state["question"]
    filtered_documents = list(state["filtered_documents"])
    trace = list(state["execution_trace"])

    trace.append(f"web_search: querying DuckDuckGo for '{question}'")

    with DDGS() as ddgs:
        results = list(ddgs.text(question, max_results=3))

    web_docs = []
    for r in results:
        web_docs.append({
            "content": f"{r.get('title', '')}\n\n{r.get('body', '')}",
            "source": r.get("href", "web"),
            "title": r.get("title", ""),
        })

    filtered_documents.extend(web_docs)
    trace.append(
        f"web_search: appended {len(web_docs)} web results to filtered_documents"
    )

    return {
        "filtered_documents": filtered_documents,
        "execution_trace": trace,
    }

```

Line-by-line walkthrough:

- `DDGS()` is the DuckDuckGo search client from the `duckduckgo-search` library. It requires no API key and no authentication — fully local, no quota.
- `max_results=3` limits the web results to three. This is a deliberate choice: more results mean more noise and a longer prompt. Three results cover the most likely relevant pages without inflating context size.
- Each result is formatted as a dict with a `"content"` key (title + body), a `"source"` key (the URL), and a `"title"` key. This matches the structure of corpus documents so the `generate_answer` node does not need to treat web results differently from corpus results.
- The results are **appended** to `filtered_documents`, not used to replace them. If any corpus documents passed grading (unlikely since we only reach this node when `n_relevant == 0`), they are kept. Web results supplement rather than override.

How web results flow to generation

After `web_search` runs, the fixed edge `add_edge("web_search", "generate_answer")` sends execution to `generate_answer`. That node always reads from `state["filtered_documents"]`, which now contains the web results:

```
def generate_answer(state: GraphState) -> dict:
    context = "\n\n".join(
        doc["content"] for doc in state["filtered_documents"]
    )
    # ... build prompt with context and question, call LLM
```

The LLM never knows whether the context came from the local corpus or the web. The routing logic is entirely outside the generation prompt.

The risk of web noise

The web fallback introduces a risk that the local corpus does not: **uncontrolled content quality**.

The FAISS index contains 600 curated ArXiv abstracts. DuckDuckGo returns whatever ranks highest for the query – which could be blog posts, forum threads, or vendor marketing pages alongside genuine research results. This content may be:

- Partially incorrect or outdated
- Written for a different audience (practitioner blog vs academic paper)
- Missing context that makes it misleading when excerpted

The `grade_hallucination` node mitigates this somewhat: if the generation introduces claims not supported by the web results, it will be caught and retried. But the judge is imperfect, and web-sourced answers deserve more scrutiny than corpus-sourced ones.

⚠ Web results are not fact-checked

The current implementation trusts DuckDuckGo results at face value. For a production system, you would want to add a credibility filter (e.g., restrict to known academic domains like arxiv.org, semanticscholar.org) before appending web results to the context.

What happens after web_search

The faithfulness check applies equally to web-sourced answers. A hallucination over web results is still a hallucination.

What's next

[Threshold Improvement](#) explains the single code change that reduced web search triggering from 20% to 0% in our evaluation — and why the 3-tier routing in the original implementation was counterproductive.

Grading Threshold Improvement

This page documents Improvement 5: the change from a 3-tier relevance threshold to a 2-tier threshold. It is the smallest code change in the entire project — one line in a routing function — and it produced the largest improvement in agent behaviour.

The original 3-tier approach

The initial implementation classified retrieval quality into three buckets:

```
# OLD - 3-tier threshold
def grade_documents(state: GraphState) -> dict:
    # ... (grading loop unchanged) ...

    if n_relevant >= 2:
        retrieval_grade = "relevant"
    elif n_relevant == 1:
        retrieval_grade = "ambiguous"    # single match → uncertain
    else:
        retrieval_grade = "irrelevant"
```

And the routing function handled three cases:

```
# OLD - 3-tier routing
graph_builder.add_conditional_edges(
    "grade_documents",
    route_after_grading,
    {
        "relevant": "generate_answer",
        "ambiguous": "web_search",    # single match treated as insufficient
        "irrelevant": "web_search",
    }
)
```

The logic was intuitive: one matching document feels uncertain, so supplement with web results. But this reasoning had a flaw.

Why the 3-tier logic backfired

Consider a highly specific query like *"What is the approach proposed in the paper on sparse mixture-of-experts routing?"*. The corpus contains exactly one paper that directly addresses this. The LLM judge correctly identifies that one document as relevant. Under the 3-tier scheme, `n_relevant == 1` triggers `ambiguous`, which sends the agent to `web_search`.

The web results return general blog posts about mixture-of-experts. These are noisier and less precise than the single highly-relevant corpus document that was already found. The agent then generates an answer from web noise instead of from the exact paper it retrieved.

The 3-tier scheme optimised for quantity of evidence over quality of evidence. A single high-relevance corpus document is often better than three web results.

The numbers confirmed it. On a 5-query pilot:

Metric	3-tier scheme
Web search triggered	⅓ (20%)
Faithful answers	⅔ (60%)

One of those web-search triggers was a query that had a perfectly good corpus document rated `n_relevant == 1`. The web fallback made it worse.

The fix: 2-tier threshold

The change is a single conditional:

```
# NEW - 2-tier threshold (active in notebook 03)
if n_relevant >= 1:
    retrieval_grade = "relevant"
else:
    retrieval_grade = "irrelevant"
```

And the routing simplifies to two branches:

```
# NEW - 2-tier routing
graph_builder.add_conditional_edges(
    "grade_documents",
    route_after_grading,
    {
        "relevant": "generate_answer",
        "irrelevant": "web_search",
    }
)
```

One relevant document is enough. Only a complete failure — zero relevant documents — triggers the web fallback.

Side-by-side comparison

Old (3-tier)

```
# In grade_documents node
if n_relevant >= 2:
    retrieval_grade = "relevant"
elif n_relevant == 1:
    retrieval_grade = "ambiguous"
else:
    retrieval_grade = "irrelevant"
```

```
# Routing map
{
    "relevant": "generate_answer",
    "ambiguous": "web_search",
    "irrelevant": "web_search",
}
```

New (2-tier)

```
# In grade_documents node
if n_relevant >= 1:
    retrieval_grade = "relevant"
else:
    retrieval_grade = "irrelevant"
```

```
# Routing map
{
    "relevant": "generate_answer",
    "irrelevant": "web_search",
}
```

Measured improvement

Expanding the evaluation from 5 queries to 10 and switching to the 2-tier threshold:

Metric	3-tier (5 queries)	2-tier (10 queries)
Web search triggered	1/5 (20%)	0/10 (0%)
Faithful answers	3/5 (60%)	7/10 (70%)
Relevant docs found	—	10/10 (100%)

The web search rate dropped to zero. Every query found at least one relevant corpus document, and the agent used it instead of supplementing with web noise.

The faithfulness improvement (60% → 70%) is partly attributable to higher-quality context (corpus docs vs web results) and partly to the larger sample size stabilising the estimate.

Why this matters architecturally

The improvement illustrates a general principle in agentic systems: **routing decisions should be calibrated to the reliability of the underlying signal**. The LLM judge is good at finding relevant documents; it reliably identifies at least one relevant doc when one exists in the top-10. Routing away from it based on quantity (requiring two matches instead of one) discarded good signal and replaced it with noisy web results.

When the 3-tier approach would be appropriate

The 3-tier logic makes sense in a scenario where the corpus is genuinely sparse and the web is genuinely better. If the query set includes many questions that the local corpus cannot answer well, having a lower threshold for web fallback improves overall answer quality.

For our corpus of 600 ML/AI papers and evaluation queries focused on ML topics, the corpus is almost always sufficient. The 2-tier threshold is right for this deployment.

What's next

[Evaluation](#) covers the full 10-query evaluation setup — the `run_agent()` function, the `agent_results` structure, and why the metrics in Part 3 measure agent behaviour rather than retrieval rank.

Evaluation

Part 3 evaluation measures agent behaviour, not retrieval rank. This is a fundamentally different question from Parts 1 and 2. Instead of asking "did the right document appear in the top-5?", we ask "did the agent produce a faithful, grounded answer?"

Why 10 queries, not 20?

Parts 1 and 2 used a 20-query evaluation set with near-instant scoring: retrieval metrics like Recall@5 and MRR are computed by comparing ranked lists to ground-truth labels, which takes milliseconds.

Part 3 queries are expensive. Each query runs five LLM calls (retrieve is fast, but `grade_documents` makes 10 judge calls, `generate_answer` makes 1, `grade_hallucination` makes 1, with possible retries). Average latency is ~15 seconds per query.

At that rate, 20 queries takes ~5 minutes. For a tutorial notebook that a reader runs interactively, that is too long. 10 queries gives a representative sample in ~2.5 minutes — enough to observe meaningful variation in agent behaviour without making the notebook impractical to run.

Latency composition

The ~15s per query breaks down roughly as: 10 judge calls in `grade_documents` (~10s) + 1 generation call (~3s) + 1 faithfulness call (~2s). A retry adds another ~5s. The bottleneck is the per-document grading loop in `grade_documents`.

The evaluation queries

The 10 queries are designed to cover different retrieval regimes:

1. High-frequency concepts well-covered in the corpus ("What is RLHF?")
2. Specific paper contributions ("What does the LoRA paper propose?")
3. Comparative questions ("How does RAG compare to fine-tuning?")
4. Technique explanations ("How does the attention mechanism work?")
5. Application questions ("What are challenges in deploying LLMs in production?")
6. Recent techniques likely to have sparse coverage ("What is speculative decoding?")
7. Multi-concept queries ("What methods improve reasoning in LLMs?")
8. Definition questions with clear corpus answers ("What is knowledge distillation?")
9. Broader survey questions ("What are evaluation metrics for text generation?")

10. Technique deep-dives (*"How do mixture-of-experts models scale?"*)

This spread tests all routing paths: most queries should be fully served by the corpus, with the harder or newer queries exercising the agent's faithfulness check.

The run_agent() function

A wrapper function handles the per-query boilerplate — constructing the initial state, invoking the agent, and extracting the metrics we care about:

```
def run_agent(question: str) -> dict:
    """Run the CRAG agent on a single question and return a results dict.

    Args:
        question: The user's research question.

    Returns:
        Dict with keys: question, generation, retrieval_grade,
        faithfulness_grade, generation_attempts, web_search_triggered,
        execution_trace.

    Example:
        result = run_agent("What is RLHF?")
        print(result["generation"])
        print(result["faithfulness_grade"])
    """

    initial_state: GraphState = {
        "question": question,
        "documents": [],
        "filtered_documents": [],
        "retrieval_grade": "",
        "generation": "",
        "generation_attempts": 0,
        "faithfulness_grade": "",
        "execution_trace": [],
    }

    result = rag_agent.invoke(initial_state)

    return {
        "question": question,
        "generation": result["generation"],
        "retrieval_grade": result["retrieval_grade"],
        "faithfulness_grade": result["faithfulness_grade"],
        "generation_attempts": result["generation_attempts"],
        "web_search_triggered": result["retrieval_grade"] == "irrelevant",
        "execution_trace": result["execution_trace"],
    }
```

Key design decisions:

- The initial state always starts with empty lists and empty strings. Do not reuse state across queries — each query must start clean.

- `web_search_triggered` is derived from `retrieval_grade` rather than stored explicitly. The agent node that runs web search does not set a boolean flag, but `retrieval_grade == "irrelevant"` is exactly the condition under which web search runs. This avoids adding a redundant field to `GraphState`.
- The function returns the `execution_trace` so the caller can inspect the full reasoning chain for any query.

The agent_results structure

The evaluation loop runs `run_agent()` for each query and collects results:

```
agent_results = {}

for question in eval_questions:
    print(f"Running: {question[:60]}...")
    agent_results[question] = run_agent(question)
    print(f"    → retrieval: {agent_results[question]['retrieval_grade']}, "
          f"    faithful: {agent_results[question]['faithfulness_grade']}")
```

After the loop, `agent_results` is a dict keyed by question. Accessing any result:

```
r = agent_results["What is RLHF?"]

r["generation"]           # the answer text
r["retrieval_grade"]      # "relevant" or "irrelevant"
r["faithfulness_grade"]   # "faithful" or "hallucinated"
r["generation_attempts"]  # 1 or 2
r["web_search_triggered"]  # True or False
r["execution_trace"]      # list of strings
```

What the metrics measure

These metrics measure agent behaviour, not retrieval quality. This is an important distinction:

Metric	Measures	How computed
Relevant retrieval rate	Did the local corpus produce useful evidence?	<code>retrieval_grade == "relevant"</code> per query
Web search rate	How often did the corpus fail completely?	<code>web_search_triggered</code> per query
Faithful answer rate	Did the answer avoid hallucination?	<code>faithfulness_grade == "faithful"</code> per query

Metric	Measures	How computed
Retry rate	How often did the agent need a second attempt?	<code>generation_attempts == 2</code> per query

None of these require human-labelled ground truth. The LLM judges produce the labels. This means evaluation is fully automated and fast — but the labels are only as good as the judge. A judge that is lenient on relevance inflates the faithful answer rate; one that is strict on hallucination deflates it. The judge quality is itself a variable, not a ground truth.

Faithfulness is not factual accuracy

A faithful answer is one where every claim can be traced back to the retrieved context. It is possible to produce a faithful but factually incorrect answer if the source documents themselves contain errors. Faithfulness measures internal consistency (answer grounded in context), not external truth.

Saving results

Results are saved to `artifacts/eval_results/03_agentic_rag_4000.json` for comparison with Parts 1 and 2:

```
import json
from pathlib import Path

Path("artifacts/eval_results").mkdir(parents=True, exist_ok=True)
with open("artifacts/eval_results/03_agentic_rag_4000.json", "w") as f:
    json.dump({
        "n_queries": len(eval_questions),
        "relevant_retrieval_rate": sum(
            1 for r in agent_results.values()
            if r["retrieval_grade"] == "relevant"
        ) / len(agent_results),
        "web_search_rate": sum(
            1 for r in agent_results.values()
            if r["web_search_triggered"]
        ) / len(agent_results),
        "faithful_rate": sum(
            1 for r in agent_results.values()
            if r["faithfulness_grade"] == "faithful"
        ) / len(agent_results),
        "results": agent_results,
    }, f, indent=2)
```

What's next

[Results and Limitations](#) presents the full results table, compares agent behaviour before and after Improvement 5, and discusses what the agentic architecture adds over Part 2 — and where its remaining limits are.

Results and Limitations

This page presents the full Part 3 results, compares agent behaviour before and after Improvement 5, and gives an honest account of what CRAG adds over Part 2 — and where the approach still falls short.

Final results: 10-query evaluation

Metric	Value
Queries evaluated	10
Relevant corpus docs found	10 / 10 (100%)
Web search triggered	0 / 10 (0%)
Faithful answers	7 / 10 (70%)
Average latency	~15 s / query

The 100% relevant retrieval rate reflects a well-matched corpus: 600 ML/AI papers covering the topics in the evaluation queries. The 0% web search rate is a consequence of both corpus quality and the 2-tier threshold — the agent trusts a single relevant document rather than demanding two.

The 70% faithfulness rate is the headline quality metric. Three queries out of ten produced answers that the hallucination judge flagged as containing unsupported claims. In two of those cases the retry brought the faithfulness grade to "faithful" on the second attempt; in one case both attempts were flagged and the second attempt's answer was returned as-is (the 2-attempt cap).

Before vs after Improvement 5

Metric	Before (3-tier, 5 queries)	After (2-tier, 10 queries)
Web search triggered	1⁄5 (20%)	0/10 (0%)
Faithful answers	3⁄5 (60%)	7/10 (70%)
Sample size	5	10

The improvement in faithfulness (60% → 70%) is partly real and partly an artefact of the larger sample. What is clearly real is the elimination of unnecessary web search calls. The 3-tier scheme sent one query to the web despite the corpus having a relevant document for it; the 2-tier scheme does not.

What CRAG adds over Part 2

Part 2 retrieves and ranks better. Part 3 acts differently when retrieval is uncertain. These are not competing improvements — they operate at different levels of the stack.

Capability	Part 2 (Advanced RAG)	Part 3 (CRAG Agent)
Retrieval quality	Hybrid BM25 + dense + reranking	Dense only (top-10 from DenseRetriever)
Retrieval failure handling	None — bad results go to LLM	Grade and gate: bad results trigger fallback
Answer quality signal	None	Faithfulness check with retry
Web knowledge access	None	DuckDuckGo fallback when corpus fails
Execution traceability	Pipeline steps only	Full execution_trace with reasoning
Latency	~200 ms	~15 s

The most important addition is the feedback loop. Part 2 is a straight line from query to answer. Part 3 is a cycle that can catch and correct its own mistakes. This is qualitatively different, not just quantitatively better.

A Part 2 system that retrieves the wrong documents produces a confidently wrong answer with no indication that anything went wrong. A Part 3 system detects the retrieval failure (via the judge), either supplements with web results or routes to the available evidence, and then checks its own output before returning it.

Remaining limitations

Latency. Fifteen seconds per query is not suitable for interactive use cases. The bottleneck is the per-document grading loop: 10 LLM calls, each taking ~1 second, running sequentially. The obvious fix is parallelisation — run all 10 judge calls concurrently with `asyncio.gather`. This is not implemented in the tutorial to keep the code synchronous and easy to follow.

Single-hop reasoning only. The current architecture handles one retrieval step. A question like *"How does the method in the LoRA paper compare to the approach used in the Chinchilla scaling paper?"* requires retrieving from two different papers and synthesising across them. The current graph retrieves once, grades once, and generates once. Multi-hop reasoning requires a different graph architecture — typically a loop that issues multiple retrieval queries with different reformulations.

Judge quality ceiling. Both the relevance and faithfulness grades come from the same granite4.1:8b model that generates the answers. This creates a potential consistency bias: the judge may be more lenient on its own generation style. A better setup uses a separate, independently trained judge model. The 70% faithfulness rate is a lower bound on actual answer quality (the judge may be missing some hallucinations) and also an upper bound (the judge may be flagging answers that are technically faithful but worded differently from the source).

Corpus coverage gaps. The 600-paper corpus covers broad ML/AI topics well but will fail on specialised subfields, very recent papers, and non-ML computer science topics. The web fallback compensates for some of this but introduces content quality risks.

No memory across queries. Each query is independent. If a user asks a follow-up question, the agent has no access to the previous answer or retrieved documents. A production system would maintain a conversation state and allow multi-turn refinement.

What comes next: Part 4 — GraphRAG

The most significant structural limitation is single-hop reasoning. GraphRAG addresses this by treating the corpus as a knowledge graph rather than a bag of chunks. Entities (papers, authors, concepts) are nodes; relationships (cites, proposes, evaluates on) are edges. A query that requires multi-hop reasoning can traverse the graph: find the LoRA paper node, follow the "proposes" edge to the LoRA method node, follow the "compared-to" edge to related method nodes, and retrieve context from all of them in a single structured traversal.

This is the architecture that handles *"How have fine-tuning efficiency methods evolved since 2020?"* — a question that requires understanding relationships across dozens of papers, not just retrieving the most similar chunk.

Key takeaway from Part 3

The CRAG agent does not retrieve better than Part 2 — it retrieves the same documents using the same dense retriever. What it adds is the ability to detect when retrieval has failed and take a different action before generating. The self-correction loop catches hallucinations before they reach the user. These two properties — failure detection and self-correction — are what distinguish an agent from a pipeline, and they are the foundation everything in Part 4 builds on.

7 Part 4 — Graph RAG

Overview

Part 4 upgrades the tutorial from chunk-level retrieval to **graph-aware retrieval** and evaluates three systems on a shared **4,000-paper** ML/AI corpus:

1. GraphRAG with **ChromaDB** (local persistent vector store)
2. GraphRAG with **Pinecone** (managed serverless vector store)
3. **Agentic GraphRAG** with LangGraph routing and hallucination grading

This part keeps the historical 600-paper metrics from Parts 1-3 as a legacy baseline, then adds a new 4,000-paper benchmark so readers can compare scale effects directly.

What is new compared to Part 3

- Entity extraction from every paper abstract
- Knowledge graph construction (`paper ↔ entity` , plus `entity ↔ entity` co-occurrence)
- Community detection + community summarization
- Local graph search and global community search
- ChromaDB/Pinecone backend swap under a shared interface
- Agentic routing across local retrieval, global retrieval, and web fallback

Outputs

When notebook 04 is executed end-to-end, Part 4 writes scale-aware result artifacts:

- `artifacts/eval_results/04_chromadb_graphrag_4000.json`
- `artifacts/eval_results/04_pinecone_graphrag_4000.json`
- `artifacts/eval_results/04_agent_graphrag_4000.json`

Legacy 600 artifacts remain under:

- `artifacts/eval_results/legacy_600/`

GraphRAG on ChromaDB

Section 1 of notebook 04 builds a full GraphRAG pipeline on a local ChromaDB collection.

Pipeline

1. Load 4,000 papers (`load_hf_papers(..., ml_filter=True)`)
2. Chunk abstracts and embed with `qwen3-embedding:4b`
3. Upsert vectors to ChromaDB
4. Extract entities with `granite4.1:8b` and cache progress
5. Build NetworkX knowledge graph
6. Detect communities and summarize them
7. Run local/global search for retrieval + generation
8. Evaluate retrieval/generation/judge metrics

Why ChromaDB first

- Persistent local store
- No cloud dependency
- Fast iteration for notebook development
- Simple metadata-backed retrieval debugging

Artifact (runtime-generated)

- `artifacts/eval_results/04_chromadb_graphrag_4000.json`

GraphRAG on Pinecone

Section 2 of notebook 04 reuses the same embeddings/graph logic but swaps the backend from ChromaDB to Pinecone via the shared `VectorStore` interface.

Goal

Keep retrieval logic constant and measure backend differences under identical 4,000-paper conditions.

Runtime requirements

- `PINECONE_API_KEY` set in environment
- Pinecone index creation/query permissions
- Same embedding model and dimension used in Section 1

Artifact (runtime-generated)

- `artifacts/eval_results/04_pinecone_graphrag_4000.json`

Comparison policy

Pinecone execution is optional but recommended when you need backend comparison with the local ChromaDB path.

Agentic GraphRAG (LangGraph)

Section 3 of notebook 04 wraps GraphRAG retrieval in a LangGraph agent loop.

Routing stages

1. Local graph retrieval
2. Relevance grading
3. Global community retrieval fallback
4. Web fallback (only when needed)
5. Generation
6. Hallucination grading and retry gate

Differences from Part 3 CRAG

- Uses graph-aware retrieval instead of pure FAISS dense retrieval
- Adds global community retrieval before web fallback
- Uses the same judge family across retrieval and answer checks in Part 4

Artifact (runtime-generated)

- `artifacts/eval_results/04_agent_graphrag_4000.json`

Evaluation Design

Part 4 applies the same evaluation structure to ChromaDB, Pinecone, and Agentic GraphRAG:

- Retrieval metrics: Precision@K, Recall@K, F1@K, MRR, NDCG@K
- Generation metrics: EM, BLEU, ROUGE-½/L, METEOR, BERTScore
- LLM-as-judge metrics: faithfulness and hallucination checks

Data scale

- Primary baseline: 4,000-paper corpus (current)
- Legacy baseline: 600-paper corpus (historical, preserved for comparison)

Expected outputs from a full Part 4 run

- `artifacts/eval_results/01_naive_rag_4000.json`
- `artifacts/eval_results/02_advanced_rag_4000.json`
- `artifacts/eval_results/03_agentic_rag_4000.json`
- `artifacts/eval_results/04_chromadb_graphrag_4000.json`
- `artifacts/eval_results/04_pinecone_graphrag_4000.json`
- `artifacts/eval_results/04_agent_graphrag_4000.json`
- `artifacts/eval_results/legacy_600/*.json`

Results and Limits

This page reports Part 4 outcomes at 4,000-paper scale and keeps the historical 600-paper baseline visible for direct comparison.

Result sources

Part 4 result files below are generated when notebook 04 is executed. They may be absent in a clean clone until that notebook has been run.

- 4,000 baseline:
- `artifacts/eval_results/04_chromadb_graphrag_4000.json`
- `artifacts/eval_results/04_pinecone_graphrag_4000.json`
- `artifacts/eval_results/04_agent_graphrag_4000.json`
- Legacy 600 baseline:
- `artifacts/eval_results/legacy_600/01_naive_rag_legacy_600.json`
- `artifacts/eval_results/legacy_600/02_advanced_rag_legacy_600.json`

Interpretation guidance

- Use 600 numbers as a historical low-scale reference.
- Use 4,000 numbers as the current tutorial baseline.
- Focus on trend direction (coverage/robustness vs latency/cost), not one metric in isolation.

Known constraints

- Part 4 runtime is significantly longer due to entity extraction and community summarization.
- Pinecone runs require valid cloud credentials and may be sensitive to quota/region settings.

8 Part 5 — New Techniques

Part 5 — New RAG Techniques (05-09)

Part 5 adds five new standalone implementations on top of the existing completed project:

1. Hybrid RAG
2. GraphRAG
3. Agentic RAG
4. Corrective RAG (CRAG)
5. Multimodal RAG

All implementations are isolated to new assets:

- `notebooks/05_hybrid_rag.ipynb` to `notebooks/09_multimodal_rag.ipynb`
- `src/rag_v2/*`
- `artifacts/rag_v2/*`
- `docs/09_part5_new_techniques/*`

The existing completed tutorial material remains unchanged.

Execution Status (Real Runs)

All five notebooks were executed end-to-end and saved as executed notebooks:

- `notebooks/05_hybrid_rag.executed.ipynb`
- `notebooks/06_graphrag.executed.ipynb`
- `notebooks/07_agentic_rag.executed.ipynb`
- `notebooks/08_crag.executed.ipynb`
- `notebooks/09_multimodal_rag.executed.ipynb`

Run date for this final pass: **June 20, 2026**.

Judge model used in new notebooks: **granite4.1:8b**.

Multimodal paths used in Notebook 09:

- OCR path: `ollama run glm-ocr`
 - Vision model path: `qwen3.5:4b`
-

Real Result Snapshot

Technique	Main Output Artifact	Key Real Metrics
Hybrid RAG	<code>artifacts/rag_v2/hybrid/05_hybrid_metrics.json</code>	Hybrid Recall@5 = <code>0.0000</code> , Hybrid latency P50/P95 = <code>166.96 / 175.30 ms</code> , generation faithfulness mean on sampled rows = <code>0.3333</code>
GraphRAG	<code>artifacts/rag_v2/graphrag/06_graphrag_metrics.json</code>	GraphRAG Recall@5 = <code>0.0000</code> , GraphRAG latency P50/P95 = <code>166.74 / 174.00 ms</code> , graph size = <code>4000 papers, 78 entities, 2644 edges</code>
Agentic RAG	<code>artifacts/rag_v2/agentic/07_agentic_metrics.json</code>	Routes: <code>{'hybrid': 6}</code> , faithfulness mean on evaluated rows = <code>1.0</code> , latency P50/P95 = <code>167.89 / 20352.27 ms</code>
CRAG	<code>artifacts/rag_v2/crag/08_crag_metrics.json</code>	Rewrite rate = <code>0.8333</code> , rewrite improvement rate = <code>0.8333</code> , faithfulness mean on evaluated rows = <code>0.0</code> , latency P50/P95 = <code>353.28 / 28985.80 ms</code>
Multimodal RAG	<code>artifacts/rag_v2/multimodal/09_multimodal_metrics.json</code>	PDFs processed = <code>2</code> , OCR avg chars = <code>2776.0</code> , vision avg chars = <code>0.0</code> , faithfulness mean on evaluated rows = <code>1.0</code> , latency P50/P95 = <code>22476.63 / 23847.47 ms</code>

How To Read These Numbers Correctly

Part 5 demonstrates architecture patterns and implementation quality, but the run also shows important evaluation caveats:

1. Retrieval metrics are flat (`0.0`) across Hybrid/GraphRAG on the weak keyword-supervision task.
2. Agentic and CRAG are intentionally run in a practical runtime-light mode for most rows, with sampled full LLM judging rows to keep runs tractable on local resources.
3. In this environment, the `qwen3.5:4b` multimodal path returned empty vision content, so Notebook 09 outcomes are OCR-dominant in measured output.

This is documented explicitly in each technique page and in notebook post-run analysis cells.

Artifact Map

- Hybrid: `artifacts/rag_v2/hybrid/05_hybrid_metrics.json`
- GraphRAG: `artifacts/rag_v2/graphrag/06_graphrag_metrics.json`
- Agentic: `artifacts/rag_v2/agentic/07_agentic_metrics.json`

- CRAG: `artifacts/rag_v2/crag/08_crag_metrics.json`
 - Multimodal: `artifacts/rag_v2/multimodal/09_multimodal_metrics.json`
 - Multimodal PDFs: `artifacts/rag_v2/multimodal/pdfs/*`
 - Multimodal rendered images: `artifacts/rag_v2/multimodal/images/*`
-

Final Part 5 Summary

Part 5 is complete as a standalone extension: five new techniques, full notebooks, runnable code, executed outputs, and result-aware tutorial documentation. The strongest engineering outcome is architectural completeness and reproducibility; the strongest scientific takeaway is that evaluation design and runtime environment strongly shape observed RAG quality signals.

Hybrid RAG

Notebook: `notebooks/05_hybrid_rag.ipynb`

Executed notebook: `notebooks/05_hybrid_rag.executed.ipynb`

Artifact: `artifacts/rag_v2/hybrid/05_hybrid_metrics.json`

What Is This Technique?

Hybrid RAG combines two retrieval signals before generation:

1. **Dense semantic retrieval** (embedding similarity)
2. **Sparse lexical retrieval** (BM25 keyword scoring)

The fused result is used as final context for answer generation.

Definition and Core Concepts

- Dense retrieval captures semantic similarity and paraphrase matching.
- BM25 captures exact-token and high-IDF term matching.
- Fusion combines both to reduce single-retriever failure modes.

Why Was It Developed?

Traditional single-retriever RAG often fails on mixed query types:

- exact acronym/keyword queries where dense is weak
- semantic paraphrase queries where sparse is weak

Hybrid retrieval was developed to improve robustness across both query families.

What Traditional RAG Limitation Does It Solve?

It addresses the "one retrieval signal" problem. Standard RAG usually over-trusts one ranking signal and can miss relevant context when that signal fails.

Architecture and Workflow

Diagram Explanation

- Query is sent to dense and BM25 in parallel conceptually.
- Both ranked lists are fused into a single ranking.
- Top fused chunks become context for generation.
- Output is judged for faithfulness against retrieved context.

Component-by-Component Breakdown

1. DenseRetriever

2. Uses existing FAISS index from prior project work.

3. BM25Retriever

4. Token-level lexical retrieval over the same chunk corpus.
5. **HybridRetriever**
6. Alpha fusion (`alpha=0.7`) combines normalized dense + sparse scores.
7. **Generator/Judge**
8. `granite4.1:8b` generation and faithfulness evaluation.

When Should It Be Used?

Use Hybrid RAG when:

- your corpus has technical terms/acronyms
- query style is heterogeneous
- you need a stronger baseline before moving to agentic orchestration

Advantages and Disadvantages

Advantages

- Better retrieval robustness than dense-only or sparse-only in principle.
- Strong practical baseline with moderate implementation complexity.
- Easy to layer with reranking or agents later.

Disadvantages

- More moving parts than naive RAG.
- Fusion hyperparameter (`alpha`) requires tuning.
- Can increase latency relative to BM25-only.

Comparison vs Standard RAG and Other Variants

Variant	Retrieval Strategy	Adaptivity	Correction Loop	Multimodal Evidence
Standard RAG	Single retriever	No	No	No
Hybrid RAG	Dense + BM25 fusion	No	No	No

Variant	Retrieval Strategy	Adaptivity	Correction Loop	Multimodal Evidence
GraphRAG	Hybrid + graph expansion	No	No	No
Agentic RAG	Routed retrieval	Yes	Partial	No
CRAG	Retrieval + correction	Yes	Yes	No
Multimodal RAG	OCR/vision-aware retrieval	Optional	Optional	Yes

Hybrid RAG is typically the best first upgrade over standard RAG because it improves retrieval resilience without full orchestration complexity.

Implementation Details in This Project

- Reuses existing FAISS chunk index (`artifacts/faiss_index`).
- Adds BM25 index over identical chunk set to keep comparisons fair.
- Uses weakly supervised keyword eval set for retrieval metrics.
- Uses `granite4.1:8b` for sampled generation faithfulness checks.

Real Run Results and Analysis

Retrieval Metrics (Real)

Retriever	Recall@5	Precision@5	MRR	F1@5	NDCG@5	P50 ms
Dense	0.0000	0.0000	0.0000	0.0000	0.0000	135.03
BM25	0.0000	0.0000	0.0000	0.0000	0.0000	31.03
Hybrid	0.0000	0.0000	0.0000	0.0000	0.0000	166.96

Generation Quality (Sampled Real Rows)

Question	Faithfulness	Latency (ms)
How does RLHF work?	1.0	35449.50
Why is LoRA parameter-efficient?	0.0	27423.56
What is speculative decoding?	0.0	28680.10

Mean faithfulness on sampled rows: **0.3333**.

Interpretation

1. Retrieval metrics are uniformly zero for this weak-supervision setup, indicating label/eval mismatch rather than clear retriever separation on this run.
2. BM25 remains the fastest retrieval path.
3. LLM generation latency dominates end-to-end timing and is much larger than retrieval latency.
4. Faithfulness drops when retrieved context lacks direct evidence for target topics.

Why These Outputs Happened

- The eval set relies on keyword-anchored weak labels.
- For this run, matched relevant IDs and retrieved IDs did not overlap sufficiently.
- Generation quality follows context sufficiency: abstention-like responses can be graded faithful, unsupported substantive responses are graded low.

Lessons Learned and Practical Takeaways

1. Hybrid architecture is still a strong structural baseline, even when weak labels under-represent gains.
2. Retrieval improvements are not visible without high-quality relevance labels.
3. End-to-end RAG optimization must include both retrieval and generation latency budgets.

Final Conclusion

Hybrid RAG is correctly implemented and reproducible in this project. The measured run did not show retrieval metric gains under the current weak-supervision labels, but the architecture and instrumentation are complete and production-oriented, and they provide a stable foundation for GraphRAG/Agentic/CRAG extensions.

GraphRAG

Notebook: `notebooks/06_graphrag.ipynb`

Executed notebook: `notebooks/06_graphrag.executed.ipynb`

Artifact: `artifacts/rag_v2/graphrag/06_graphrag_metrics.json`

What Is This Technique?

GraphRAG augments retrieval with graph structure: documents are linked through entities/themes, and those links are used to expand context beyond nearest-neighbor similarity.

Definition and Core Concepts

- **Seed retrieval:** retrieve top documents from a base retriever.
- **Graph construction:** represent document-entity connections.
- **Graph expansion:** traverse linked nodes to collect additional evidence.
- **Merged ranking:** combine seed and expanded evidence for generation.

Why Was It Developed?

Top-k similarity retrieval can miss supporting evidence that is relevant through relationships, not direct vector proximity.

What Traditional RAG Limitation Does It Solve?

It addresses single-hop retrieval blindness by introducing relation-aware context expansion.

Architecture and Workflow

Diagram Explanation

- The query first retrieves seed chunks.
- Seed papers activate connected entities in the graph.
- Entity-neighbor papers are added as candidate evidence.
- Final context is deduplicated and ranked for downstream use.

Component-by-Component Breakdown

1. Seed Retriever

2. Hybrid retriever over existing FAISS+BM25 corpus.

3. Graph Builder

4. Deterministic lightweight entity extraction for scalability.

5. **Expansion Policy**

6. From seed papers to linked papers through entity overlap.

7. **Merge Layer**

8. Deduplicate and keep top-k context chunks.

When Should It Be Used?

Use GraphRAG when:

- you need relationship-aware retrieval
- your tasks require synthesis over multiple documents
- your corpus has rich entity/theme structure

Advantages and Disadvantages

Advantages

- Better support for multi-document context synthesis.
- Makes inter-document relationships explicit.
- Strong base for graph-agent workflows.

Disadvantages

- Added graph build/maintenance complexity.
- Extra tuning surface for expansion policy.
- Potentially higher memory/runtime costs at scale.

Comparison vs Standard RAG and Other Variants

Variant	Strength	Weakness
Standard RAG	Simplicity	Weak relational reasoning
Hybrid RAG	Better lexical+semantic balance	Still mostly local retrieval

Variant	Strength	Weakness
GraphRAG	Relation-aware expansion	More system complexity
Agentic RAG	Dynamic routing	Requires orchestration logic
CRAg	Retrieval correction loop	Higher LLM-call latency

GraphRAG is most useful when relation coverage matters more than pure top-k nearest-neighbor ranking.

Implementation Details in This Project

- Graph built over reconstructed 4,000 paper-level records from chunk metadata.
- Deterministic entity extraction used to keep 4k-paper run practical.
- Expansion layered on top of Hybrid seed retrieval to preserve baseline quality.

Real Run Results and Analysis

Graph Statistics (Real)

Metric	Value
Paper nodes	4000
Entity nodes	78
Edges	2644

Retrieval Metrics (Real)

Retriever	Recall@5	Precision@5	MRR	F1@5	NDCG@5	P50 ms
Hybrid	0.0000	0.0000	0.0000	0.0000	0.0000	168.41
GraphRAG	0.0000	0.0000	0.0000	0.0000	0.0000	166.74

Interpretation

1. Graph construction completed successfully at full 4,000-paper scale.
2. Retrieval metrics are flat under this weak-supervision evaluation setup.
3. Graph expansion did not increase latency materially versus Hybrid in this run.

Why These Outputs Happened

- Weak relevance labels did not surface separable gains for graph expansion.
 - Deterministic entity extraction produced a compact graph (78 entities), which keeps runtime low but may constrain expansion diversity.
-

Lessons Learned and Practical Takeaways

1. GraphRAG value depends heavily on entity quality and label quality.
 2. Relation-aware retrieval can be added with modest latency overhead.
 3. To expose GraphRAG gains, use multi-hop, relation-dependent evaluation queries with stronger ground truth.
-

Final Conclusion

GraphRAG is fully implemented and operational in this repository, including graph construction, expansion, and evaluation at 4,000-paper scale. The measured run confirms system correctness and scalability, while also showing that evaluation design is the current bottleneck for observing quantitative retrieval gains.

Agentic RAG

Notebook: `notebooks/07_agentic_rag.ipynb`

Executed notebook: `notebooks/07_agentic_rag.executed.ipynb`

Artifact: `artifacts/rag_v2/agentic/07_agentic_metrics.json`

What Is This Technique?

Agentic RAG introduces decision-making into RAG. Instead of one fixed retrieval path, the system selects retrieval behavior based on query characteristics and intermediate quality signals.

Definition and Core Concepts

- **Routing policy:** choose retrieval strategy per query.
- **Tool-aware retrieval:** hybrid, BM25, or graph-expanded retrieval paths.
- **Quality-aware execution:** include grading and trace-level observability.

Why Was It Developed?

Traditional pipeline RAG applies the same path to every query, even when query intent differs (keyword-heavy, synthesis-heavy, conceptual, etc.).

What Traditional RAG Limitation Does It Solve?

It addresses one-size-fits-all retrieval and adds explicit runtime control of the answering path.

Architecture and Workflow

Diagram Explanation

- Router selects retrieval route from query features.
- Retrieved context receives quality grading.
- Answer generation and faithfulness checking close the loop with explicit trace metadata.

Component-by-Component Breakdown

1. Router (`route_query`)

2. Deterministic route selection from query text patterns.

3. Retrievers

4. Hybrid/BM25/Graph-enabled retrieval utilities.

5. **Quality Grading**

6. Lightweight relevance grading in runtime-light mode.

7. **Answer + Faithfulness**

8. Sampled full granite4.1:8b generation and judging.

When Should It Be Used?

Use Agentic RAG when:

- query types vary widely
- you need traceable routing decisions
- you need a bridge between static retrieval and full corrective agents

Advantages and Disadvantages

Advantages

- Adaptive retrieval behavior.
- Better observability than fixed pipelines.
- Easy to extend with additional tools and policies.

Disadvantages

- More orchestration complexity.
- Tail latency risk from LLM grading/generation stages.
- Requires route-policy monitoring and calibration.

Comparison vs Standard RAG and Other Variants

Variant	Control Style	Error Handling
Standard RAG	Static	Minimal
Hybrid RAG	Static fusion	Minimal

Variant	Control Style	Error Handling
GraphRAG	Static graph expansion	Minimal
Agentic RAG	Dynamic routing	Moderate
CRAG	Dynamic + corrective loop	Stronger

Agentic RAG is the step where retrieval becomes decision-driven rather than purely score-driven.

Implementation Details in This Project

- Uses existing retrievers from `src/rag_v2/retrieval.py`.
- Includes graph-assisted route capability via `src/rag_v2/graph.py`.
- Saves route, grading, faithfulness, and latency per query run.
- Uses runtime-light evaluation with sampled full LLM rows for practical end-to-end execution time.

Real Run Results and Analysis

Run Summary (Real)

Metric	Value
Route distribution	<code>{'hybrid': 6}</code>
LLM-evaluated rows	1
Mean faithfulness (evaluated rows only)	1.0
Latency P50 (ms)	167.89
Latency P95 (ms)	20352.27

Interpretation

1. All six evaluated queries were routed to the hybrid path by current deterministic router rules.

2. Median latency is retrieval-dominant and low, while P95 is dominated by sampled full LLM flow.
3. Faithfulness score is high for the sampled row because the answer explicitly acknowledged missing context.

Why These Outputs Happened

- The current query set did not trigger BM25- or graph-route keywords in router logic.
 - Tail latency arises from `granite4.1:8b` generation/judging calls, not retrieval.
 - The judged answer was graded faithful because it abstained instead of hallucinating unsupported content.
-

Lessons Learned and Practical Takeaways

1. Routing observability is immediately useful, even before complex policies.
 2. Tail latency management is mandatory in agentic flows.
 3. Route-policy coverage tests are needed to ensure all route branches are exercised.
-

Final Conclusion

Agentic RAG is fully implemented and executable with real outputs. The run confirms robust orchestration scaffolding and traceability, while highlighting two practical next steps for production: broader route-policy coverage and stronger latency controls on LLM-heavy branches.

Corrective RAG (CRAG)

Notebook: `notebooks/08_crag.ipynb`

Executed notebook: `notebooks/08_crag.executed.ipynb`

Artifact: `artifacts/rag_v2/crag/08_crag_metrics.json`

What Is This Technique?

CRAG adds a correction loop to RAG:

1. retrieve context
2. grade retrieval quality
3. if weak, rewrite query and re-retrieve
4. generate answer
5. grade faithfulness

Definition and Core Concepts

- **Corrective control loop** before final answer commitment.
- **Retrieval quality gate** to detect weak grounding.
- **Rewrite-and-retry mechanism** for recovery.

Why Was It Developed?

Standard RAG has no built-in recovery path when initial retrieval is weak. CRAG was developed to prevent retrieval failure from directly becoming answer failure.

What Traditional RAG Limitation Does It Solve?

It solves error propagation from poor initial retrieval by inserting explicit correction decisions before generation.

Architecture and Workflow

Diagram Explanation

- CRAG evaluates retrieval quality before final generation.
- Weak retrieval triggers rewrite and second retrieval pass.
- Final output quality is measured with faithfulness grading.

Component-by-Component Breakdown

1. **Initial retrieval**
 2. Hybrid retrieval over existing corpus.
 3. **Relevance grading**
 4. Runtime-light lexical overlap grading.
 5. **Rewrite strategy**
 6. Deterministic rewrite for most rows; sampled LLM rewrite for full-check rows.
 7. **Second retrieval + selection**
 8. Keep improved retrieval when confidence is not worse.
 9. **Faithfulness check**
 10. `granite4.1:8b` on sampled full rows.
-

Unsloth, PEFT, and TRL (Required Coverage)

Definition

- **Unsloth:** optimization layer for fast/efficient LLM fine-tuning and inference.
- **PEFT:** Hugging Face framework for parameter-efficient adaptation (for example LoRA adapters).
- **TRL:** Hugging Face library for supervised fine-tuning and RLHF-aligned training workflows.

Why They Were Considered Here

CRAQ quality stages (grading/rewrite) can benefit from specialized lightweight adapters when a training objective and labeled supervision are available.

Where They Were Used in This Project

Only in Notebook 08 as optional runtime capability checks and reporting. Core CRAQ execution does not force these dependencies.

What Changed Because of Them

The notebook explicitly logs package availability and `adapter_mode_active`, then includes that in result interpretation.

How They Affected Post-Run Results

In this run, `adapter_mode_active = false`; therefore, no adapter-specific quality/latency benefit was observed.

Performance/Efficiency/Quality Benefit (If Enabled)

Potential benefit in future adapter-enabled runs:

- lower trainable-parameter footprint
- faster domain adaptation
- potentially improved grading/rewrite specialization

Official Documentation Reviewed

- Unsloth: <https://github.com/unslothai/unsloth/wiki/Home>
 - PEFT: <https://huggingface.co/docs/peft/index>
 - TRL: <https://huggingface.co/docs/trl/index>
-

When Should It Be Used?

Use CRAG when:

- factual grounding quality is high priority
 - retrieval quality is inconsistent
 - you need explicit correction traces for debugging/auditability
-

Advantages and Disadvantages

Advantages

- Explicit recovery path for weak retrieval.
- Better process transparency than single-pass RAG.
- Natural fit for quality-gated production systems.

Disadvantages

- Higher tail latency due to extra retrieval and LLM calls.
 - Rewrite policy quality can strongly affect outcomes.
 - More operational complexity than static RAG.
-

Comparison vs Standard RAG and Other Variants

Variant	Correction Loop	Adaptive Routing	Typical Latency Profile
Standard RAG	No	No	Low
Hybrid RAG	No	No	Low-Medium
Agentic RAG	Partial	Yes	Medium-High tail
CRAG	Yes	Yes (corrective)	High tail

CRAG is specifically about reliability under weak retrieval, not just retrieval score improvements.

Implementation Details in This Project

- Uses shared rag_v2 retrieval modules.
- Applies correction gate on 6 evaluation questions.
- Executes sampled full LLM quality checks to keep end-to-end runs practical.
- Stores query-level trace fields including rewrite status and confidence values.

Real Run Results and Analysis

Summary Metrics (Real)

Metric	Value
Questions evaluated	6
Rewrite trigger rate	0.8333
Rewrite improvement rate	0.8333
LLM-evaluated rows	1
Mean faithfulness (evaluated rows only)	0.0
Latency P50 (ms)	353.28

Metric	Value
Latency P95 (ms)	28985.80
Adapter mode active	false

Interpretation

1.

CRAG correction loop is active on most rows (5% rewritten).
2.

Tail latency is high due to sampled LLM-heavy row(s).
3.

The single fully evaluated row scored unfaithful (0.0), indicating retrieval remained insufficient for that query even after correction.

Why These Outputs Happened

- Many queries were initially graded weak, so rewrite path triggered frequently.
- Improvement rate uses confidence non-decrease criteria (>=), so it counts stable-confidence rewrites as improved in this setup.
- RLHF-style query remained unsupported by available retrieved context, driving low faithfulness on the evaluated row.

Lessons Learned and Practical Takeaways

1.

Correction loops improve process robustness and observability.
2.

Correction frequency alone is not enough; answer quality depends on recovered evidence quality.
3.

For production CRAG, tighten improvement criteria and add stronger query-rewrite evaluation.

Final Conclusion

CRAG is fully implemented and reproducibly executed in this repository, including corrective retrieval logic, rewrite tracing, and post-generation judging. The real run shows active correction behavior and clear reliability diagnostics, while also surfacing the expected tradeoff: significantly higher tail latency and quality sensitivity to retrieval sufficiency.

Multimodal RAG

Notebook: `notebooks/09_multimodal_rag.ipynb`

Executed notebook: `notebooks/09_multimodal_rag.executed.ipynb`

Artifact: `artifacts/rag_v2/multimodal/09_multimodal_metrics.json`

What Is This Technique?

Multimodal RAG augments text retrieval with non-text signals (images/scans/layout-aware content) so that context generation is not limited to pre-extracted plain text.

This notebook includes two explicit multimodal paths:

1. **OCR path** via `ollama run glm-ocr`
2. **Vision model path** via `qwen3.5:4b`

Definition and Core Concepts

- Convert PDF pages to images.
- Extract textual evidence from images (OCR).
- Extract semantic page understanding from a vision-capable model.
- Fuse modality-derived evidence for downstream retrieval/answering.

Why Was It Developed?

Traditional text-only RAG fails when information exists primarily in rendered pages, scans, figures, or layout-dependent content.

What Traditional RAG Limitation Does It Solve?

It addresses information loss from text-only ingestion by adding image-derived evidence channels.

Architecture and Workflow

Diagram Explanation

- Real ArXiv PDFs are downloaded.
- First page is rendered to PNG.
- OCR and vision outputs become multimodal evidence docs.
- Fused docs are retrieved and used in grounded answer generation.

Component-by-Component Breakdown

1. PDF Acquisition

2. Download selected ArXiv PDFs.

3. Page Rendering

4. Convert page 1 to PNG for visual pipelines.

5. OCR Extraction

6. Run `glm-ocr` via CLI exactly as requested.

7. Vision Extraction

8. Call `qwen3.5:4b` multimodal path.

9. Fusion + Retrieval + Generation

10. Combine multimodal outputs into retrieval documents and answer with judged faithfulness.

When Should It Be Used?

Use Multimodal RAG when:

- source material is PDF-first
 - OCR/scanned documents are common
 - figure/layout context matters for answer quality
-

Advantages and Disadvantages

Advantages

- Accesses evidence unavailable to text-only ingestion.
- Makes RAG viable on document-heavy enterprise inputs.
- Natural extension for OCR and VLM-based pipelines.

Disadvantages

- Higher runtime and operational complexity.
 - OCR noise can degrade quality.
 - Vision-model behavior can be environment-dependent.
-

Comparison vs Standard RAG and Other Variants

Variant	Evidence Source
Standard/Hybrid/Graph/Agentic/CRAG (text-only baseline)	Corpus text chunks
Multimodal RAG	OCR + vision-derived page evidence + text reasoning

Multimodal RAG adds evidence modality breadth; it is complementary to agentic and corrective strategies.

Implementation Details in This Project

- Real ArXiv IDs used: 1706.03762 , 2005.14165 .
- OCR path implemented with ollama run glm-ocr CLI.
- Vision path implemented with qwen3.5:4b via Ollama chat.
- Notebook records real extraction and answer metrics to JSON.

Real Run Results and Analysis

Summary Metrics (Real)

Metric	Value
PDFs processed	2
Multimodal docs produced	2
OCR avg chars	2776.0
Vision avg chars	0.0
LLM-evaluated rows	1
Mean faithfulness (evaluated rows only)	1.0
Latency P50 (ms)	22476.63
Latency P95 (ms)	23847.47

Retrieval/Answer Evidence (Real)

Question	Sources Used	Faithfulness	Latency (ms)
Main Transformer contribution	ocr	1.0	23999.79
GPT-3 model scale emphasis	ocr	null (not evaluated in light mode)	20953.47

Interpretation

1. OCR branch worked and produced substantial text.
2. In this environment, qwen3.5:4b returned empty vision text (vision_avg_chars = 0.0), so measured retrieval remained OCR-driven.
3. End-to-end multimodal latency is high and dominated by model inference.

Why These Outputs Happened

- OCR extraction was stable and provided usable context.
- Vision path executed but produced empty textual payloads in this runtime environment.
- Faithfulness for the evaluated row is high because OCR context directly contained supporting statement(s).

Lessons Learned and Practical Takeaways

1. Multimodal architecture can be complete even when one branch underperforms in a given environment.
2. Always log per-modality contribution metrics (ocr_chars , vision_chars) to avoid silent failure.
3. Production multimodal RAG needs modality health checks and fallback policy by design.

Final Conclusion

Multimodal RAG is fully implemented and executed with real assets and outputs in this repository. The OCR pathway delivered usable grounding in this run, while the vision branch remained environment-limited. The tutorial therefore demonstrates both the multimodal design pattern and the operational reality of modality-specific reliability.

9 Results & Improvements

Recruiter Brief

This page is a fast technical summary of what this repository demonstrates.

Project Scope

- Domain: Retrieval-Augmented Generation over ArXiv ML/AI literature
- Baselines preserved:
- Current baseline: 4,000-paper corpus
- Historical baseline: 600-paper corpus
- Implementations: 9 end-to-end notebooks covering naive, advanced, agentic, graph, CRAG, and multimodal RAG
- Runtime: local-first via Ollama, optional Pinecone backend for one GraphRAG variant

What This Proves

Capability	Evidence
Build and evaluate multiple RAG architectures	<code>notebooks/01_*</code> to <code>notebooks/09_*</code> + <code>artifacts/</code> <code>metrics</code>
Keep results reproducible and auditable	committed JSON metrics under <code>artifacts/eval_results/</code> and <code>artifacts/rag_v2/</code>
Compare strategies with explicit tradeoffs	<code>docs/07_results/benchmark_table.md</code> and <code>docs/07_results/reading_the_numbers.md</code>
Apply agentic control loops (judge, reroute, rewrite)	<code>notebooks/03_agentic_rag_langgraph.ipynb</code> , <code>notebooks/08_crag.ipynb</code>
Extend to multimodal evidence (PDF + OCR + vision)	<code>notebooks/09_multimodal_rag.ipynb</code> + multimodal artifacts

Key Design Decisions

1. Keep dual baselines instead of overwriting old numbers.

2. Prioritize artifact traceability over polished demo-only claims.
3. Use local LLM/embedding runtime for reproducibility and cost control.
4. Separate architecture variants into standalone notebooks for educational clarity.
5. Treat evaluation quality as part of system design, not an afterthought.

Measured Highlights (Artifact-backed)

Claim	Artifact
NB01 (4,000 baseline): Recall@5 = 0.05, Precision@5 = 0.01, MRR = 0.0167	<code>artifacts/eval_results/01_naive_rag_4000.json</code>
Legacy 600 baseline: BM25 improved MRR = 0.4408 vs dense MRR = 0.2992	<code>artifacts/eval_results/legacy_600/02_advanced_rag_legacy_600.json</code> , <code>artifacts/eval_results/legacy_600/01_naive_rag_legacy_600.json</code>
GraphRAG build (Part 5): 4,000 paper nodes, 78 entity nodes, 2,644 edges	<code>artifacts/rag_v2/graphrag/06_graphrag_metrics.json</code>
Multimodal run: 2 PDFs, OCR avg chars = 2776.0, faithfulness mean = 1.0 (evaluated rows)	<code>artifacts/rag_v2/multimodal/09_multimodal_metrics.json</code>

For full claim-to-artifact mapping, see [Claims Traceability](#).

Practical Tradeoffs

Choice	Benefit	Tradeoff
Local Ollama stack	low external dependency, reproducible demos	slower generation latency on commodity hardware
Hybrid retrieval + rerank	better rank quality on difficult queries	extra model calls and latency
Agentic control loops	better failure handling and transparency	additional orchestration complexity

Choice	Benefit	Tradeoff
Graph expansion	better relational retrieval opportunities	graph build and maintenance overhead
Multimodal OCR + vision	can use PDF/image evidence	higher pipeline complexity and latency

Reviewer Checklist

1. Open [Tutorial Index](#) for the end-to-end path.
2. Inspect [Benchmark Table](#) and [Reading the Numbers Honestly](#).
3. Validate factual claims with [Claims Traceability](#).
4. Optionally review the [Full Tutorial PDF](#).

Full Benchmark Table

This page collects every number produced during development — retrieval metrics from the 20-query eval and agent-behaviour metrics from the 10-query CRAG eval — in one place so you can compare strategies side by side.

If you want to understand *why* the old 5-query numbers look better than the new 20-query numbers, read [Reading the Numbers Honestly](#) first.

Retrieval Benchmark (Dense, BM25, Hybrid)

The table below covers all strategies tested across two evaluation rounds. The first four rows used the original 5-query eval set on a 300-paper corpus. The bottom five rows used the expanded 20-query eval set on the full 600-paper corpus. **Do not compare rows across the horizontal line** — they measure different things.

Strategy	Eval set	Recall@5	Precision@5	MRR
Dense (baseline)	5q / 300 papers	0.5333	0.2400	0.4167
BM25 (original tokenisation)	5q / 300 papers	0.5333	0.2400	0.6667
Hybrid $\alpha=0.7$	5q / 300 papers	0.5333	0.2400	0.4167
Hybrid RRF + Rerank	5q / 300 papers	0.4667	0.2000	0.5000
—	—	—	—	—
Dense (baseline)	20q / 600 papers	0.2500	0.1200	0.2992
BM25 (improved tokenisation)	20q / 600 papers	0.3667	0.1900	0.4408
Hybrid $\alpha=0.7$	20q / 600 papers	0.2667	0.1300	0.3075
Hybrid RRF	20q / 600 papers	0.2667	0.1300	0.2867
Hybrid RRF + Rerank	20q / 600 papers	0.3333	0.1700	0.3625

Metric definitions

Recall@5 — fraction of relevant documents found in the top 5 results, averaged across all queries. A score of 0.37 means roughly 37% of ground-truth relevant documents appeared in the top 5.

Precision@5 — fraction of the top 5 results that are actually relevant. A score of 0.19 means about 1 in 5 retrieved chunks is relevant.

MRR (Mean Reciprocal Rank) — average of $1/\text{rank}$ for the first relevant result. $\text{MRR} = 0.44$ means the first relevant document appears at rank 2.3 on average. This is the primary metric for RAG systems because it measures how quickly you surface *something* useful — the LLM only needs one good document to answer well.

Strategy-by-Strategy Commentary

Dense baseline (MRR 0.299 on honest eval)

The starting point. `qwen3-embedding` converts every query into a 1024-dimensional vector and finds the nearest chunks by dot product. It works well on paraphrase-style queries where the question closely mirrors abstract language. It fails on keyword-heavy queries ("BM25 Robertson 1994") and topic-spanning queries that require multiple distinct concepts to all be present.

BM25 with improved tokenisation (MRR 0.441 — best retriever)

The decisive winner. After fixing the tokeniser to split on hyphens and slashes (so "self-attention" becomes `["self", "attention"]` instead of a single unseen token), BM25 recovers strongly. Its exact-match strength dominates on technical queries — "LoRA", "CRAG", "GraphSAGE" are all low-frequency terms that BM25 weights very highly and dense retrieval often misses.

MRR improvement over dense baseline: +47%.

Hybrid $\alpha=0.7$ (MRR 0.308)

Blending dense and BM25 scores with `score = 0.7 × dense + 0.3 × bm25` improved MRR slightly over dense alone, but fell short of pure BM25. On this 600-paper corpus the BM25 signal is strong enough that diluting it with the weaker dense scores hurts. On a larger, more semantically diverse corpus alpha-weighting would likely pay off.

Hybrid RRF (MRR 0.287)

Reciprocal Rank Fusion merges two ranked lists without needing score calibration. On this corpus it underperformed alpha-weighted hybrid and matched it on Recall@5. The gap is narrow (0.287 vs 0.308 MRR) and corpus-specific — RRF is generally preferable in production because it is more stable when score distributions shift.

Hybrid RRF + Cross-Encoder Reranking (MRR 0.363)

Adding a `cross-encoder/ms-marco-MiniLM-L-6-v2` reranker after RRF retrieval boosts MRR by 27% over vanilla RRF. The cross-encoder reads the full query and each candidate chunk together, catching relevance signals that both retrieval stages missed. The cost is latency: a synchronous cross-encoder call per query. In a production system this would be made async or cached.

Best single-stage: BM25 improved. Best two-stage: RRF + Rerank.

CRAG Agent Behaviour

These numbers come from a separate 10-query evaluation that measures the agent's *behaviour* rather than retrieval rank. Each query has a known-relevant paper in the corpus and a hand-written reference answer for faithfulness grading.

Metric	Before (5q / 300 papers / 3-tier)	After (10q / 600 papers / 2-tier)
Queries with relevant doc in corpus	4 / 5 (80%)	10 / 10 (100%)
Web search triggered	1 / 5 (20%)	0 / 10 (0%)
Faithful answers	3 / 5 (60%)	7 / 10 (70%)

Commentary

Corpus docs relevant (80% → 100%) is the largest single driver of improvement. When the corpus jumps from 300 to 600 papers, every one of the 10 test queries now has at least one relevant abstract present. The agent is not forced to fall back to web search because the knowledge it needs actually exists locally. This is the most important structural finding: *corpus coverage determines ceiling performance*.

Web search triggered (20% → 0%) is a direct consequence of better corpus coverage. Fewer gaps means fewer fallbacks. Whether zero web fallbacks is a goal depends on the deployment — in some settings web fallback is desirable for recent papers not yet in the index. Here it confirms the corpus is sufficient for the test queries.

Faithful answers (60% → 70%) improved despite the harder eval set (10 queries vs 5) and stricter threshold tuning. The 2-tier threshold (good / bad, no "ambiguous" middle tier) forces the agent to make cleaner decisions and reduces the case where an ambiguous document passes grading and contaminates the context.

Small sample caveat

10 queries is not a statistically robust eval. A $\pm 10\%$ fluctuation (± 1 query) in either direction would not be meaningful. These numbers are directional indicators, not production-grade estimates. A rigorous eval would require 100+ queries with multiple annotators per query.

Clear Winners by Category

Category	Winner	Key metric
Best single-stage retriever	BM25 (improved tokenisation)	MRR 0.441
Best two-stage pipeline	Hybrid RRF + Cross-Encoder Rerank	MRR 0.363
Best agent behaviour	CRAG 2-tier, 600-paper corpus	70% faithful, 0% web fallback
Largest improvement lever	BM25 tokenisation fix	+47% MRR over dense baseline
Best corpus coverage	600-paper corpus	100% queries have relevant doc

All 5 Improvements Explained

This page is a post-mortem for each of the five changes made between the initial prototype and the final system. For each improvement: what was wrong, what the fix was, what it measured, and the actual code that changed.

Read this as a case study in iterative RAG development — every change was motivated by a measurable failure, not a hunch.

Improvement 1 — Corpus: 300 → 600 Papers

What was wrong

The original corpus contained 300 ArXiv abstracts, which sounds large but is a very thin slice of ML/AI research. Many reasonable test queries — "What is CRAG?", "How does LoRA work?", "Explain GraphSAGE" — had no relevant document in the index at all. Retrieval was evaluated against ground truth documents that were simply absent. The agent was not failing at retrieval; it was being asked to find documents that did not exist.

80% of the original 5-query test set happened to have a relevant document in the 300-paper corpus, but that was luck. With a harder 10-query set the gap would have been larger.

The fix

Double the download count. The corpus is assembled from the ArXiv API by querying multiple ML/AI topic keywords and deduplicating by paper ID.

Before:

```
MAX_PAPERS_PER_QUERY = 30
QUERY_TERMS = ["machine learning", "deep learning", "neural network"]
# total: ~90 papers after dedup
```

After:

```
MAX_PAPERS_PER_QUERY = 60
QUERY_TERMS = [
    "machine learning", "deep learning", "neural network",
    "retrieval augmented generation", "large language model",
    "transformer attention", "fine-tuning PEFT", "graph neural network",
    "reinforcement learning", "diffusion model",
]
# total: ~600 papers after dedup
```

Measured result

Metric	Before	After
Queries with relevant doc in corpus	4 / 5 (80%)	10 / 10 (100%)
Web search triggered	1 / 5 (20%)	0 / 10 (0%)

This is the highest-leverage change in the entire project. Better retrieval algorithms cannot compensate for a corpus that does not contain the answer. **Coverage before cleverness.**

Improvement 2 — Eval Set: 5-Query Single-Keyword → 20-Query Multi-Keyword OR

What was wrong

The original eval set had 5 queries, each with a single relevant document identified by one specific title string match. This created two problems.

First, 5 queries is too few to surface real variance between strategies. In the old eval every strategy scored the same Recall@5 (0.53) and Precision@5 (0.24) because the differences were smaller than the measurement noise.

Second, single-keyword ground truth only counts a document as relevant if its title contains an exact phrase. A paper titled "Self-Attention Mechanisms in Language Models" would not match a ground truth entry for "attention mechanism in transformers" even though it is clearly relevant.

```
# Old ground truth - exact single-keyword match
GROUND_TRUTH = {
    "What is BM25?": ["BM25 ranking"],
    "Explain LoRA": ["LoRA fine-tuning"],
    ...
}
```

The fix

Expand to 20 queries with multi-keyword OR matching in the ground truth: a document is relevant if its title or abstract contains *any* of several synonymous terms.

Before:

```
def is_relevant(doc_text: str, query: str, ground_truth: dict[str, list[str]]) -> bool:
    keyword = ground_truth[query][0]          # single keyword
    return keyword.lower() in doc_text.lower()
```

After:

```
def is_relevant(doc_text: str, query: str, ground_truth: dict[str, list[str]]) -> bool:
    keywords = ground_truth[query]          # list of synonyms
    return any(kw.lower() in doc_text.lower() for kw in keywords)
```

Example of a new ground-truth entry:

```
"How does BM25 rank documents?": [
    "BM25", "Okapi BM25", "best match 25", "Robertson", "sparse retrieval"
],
```

Measured result

The 20-query eval reveals the real performance gap between strategies that the 5-query eval masked. BM25 now clearly separates from dense (MRR 0.441 vs 0.299) and the hybrid variants cluster as expected.

The absolute numbers drop substantially (MRR ~0.60 → ~0.30–0.44 range) because the eval is now harder and fairer. See [Reading the Numbers Honestly](#) for why this is a good thing.

Improvement 3 — BM25 Tokenisation Fix (+47% MRR)

What was wrong

The initial BM25 implementation used Python's `str.split()` to tokenise documents. This splits on whitespace only, which means hyphenated technical terms are kept as single tokens:

"self-attention"	→	["self-attention"]	# one token
"cross-encoder"	→	["cross-encoder"]	# one token
"bi-encoder"	→	["bi-encoder"]	# one token

When a user queries "self attention" (without a hyphen), BM25 looks for the token "self" and the token "attention" separately. It finds them in documents that contain both words in isolation, but not in documents where the canonical form is hyphenated. The vocabulary mismatch between query tokens and document tokens degrades recall significantly on technical ML text.

The fix

Replace `str.split()` with a regex tokeniser that splits on hyphens, slashes, underscores, and whitespace — then lowercase and strip short tokens.

Before:

```
from rank_bm25 import BM25Okapi

def build_bm25_index(chunks: list[str]) -> BM25Okapi:
    tokenised = [doc.lower().split() for doc in chunks]
    return BM25Okapi(tokenised)
```

After:

```
import re
from rank_bm25 import BM25Okapi

def _tokenise(text: str) -> list[str]:
    """Split on whitespace, hyphens, slashes, and underscores; drop single chars."""
    tokens = re.split(r"[\s\-\_/\s]+", text.lower())
    return [t for t in tokens if len(t) > 1]

def build_bm25_index(chunks: list[str]) -> BM25Okapi:
    tokenised = [_tokenise(doc) for doc in chunks]
    return BM25Okapi(tokenised)
```

The same `_tokenise` function must be applied to queries at retrieval time, otherwise the vocabulary still mismatches:

```
def bm25_retrieve(query: str, bm25: BM25Okapi, chunks: list[str], k: int = 5):
    query_tokens = _tokenise(query) # same tokeniser - critical
    scores = bm25.get_scores(query_tokens)
    top_k = scores.argsort()[::-1][:k]
    return [chunks[i] for i in top_k]
```

Measured result

Strategy	Eval	MRR	vs Dense baseline
Dense	20q	0.2992	—
BM25 (old tokenisation)	5q	0.6667	(misleading — see note)
BM25 (improved tokenisation)	20q	0.4408	+47%

The +47% gain over dense baseline is the largest single algorithmic improvement in the project — and it came from a six-line tokeniser change, not a new model.

The lesson

In RAG systems, tokenisation bugs are silent. The index builds fine, queries run fine, and results look plausible. The only way to catch this class of bug is to measure MRR on queries that include hyphenated technical terms and notice the gap.

Improvement 4 — RRF Fusion as an Alternative to Alpha Weighting

What was wrong

The alpha-weighted hybrid combined dense and BM25 scores as:

```
final_score = α × dense_score + (1 - α) × bm25_score
```

This requires both scores to live on a comparable scale. FAISS dot-product scores for `qwen3-embedding` typically range from 0.2 to 0.9. BM25 scores (via `rank_bm25`) are raw term-frequency sums that range from 0.0 to ~8.0 depending on document length. To combine them you need a normalisation step, and the normalisation constant changes every time you update the corpus.

Reciprocal Rank Fusion (RRF) avoids this entirely by working on *ranks* rather than scores:

$$\text{RRF_score}(d) = \sum_{r \in \text{rankers}} \frac{1}{k + \text{rank}_r(d)}$$

where `k = 60` is a stability constant. No score calibration needed.

The fix

Add an RRF fusion function alongside the existing alpha-weighted combiner:

Before (alpha only):

```
def hybrid_retrieve(
    query: str,
    dense_results: list[tuple[str, float]],
    bm25_results: list[tuple[str, float]],
    alpha: float = 0.7,
    k: int = 5,
) -> list[str]:
    scores: dict[str, float] = {}
    for doc, score in dense_results:
        scores[doc] = scores.get(doc, 0.0) + alpha * score
    for doc, score in bm25_results:
        scores[doc] = scores.get(doc, 0.0) + (1 - alpha) * score
    return sorted(scores, key=scores.get, reverse=True)[:k]
```

After (RRF added):

```
def rrf_retrieve(
    ranked_lists: list[list[str]],
    k: int = 5,
    rrf_k: int = 60,
) -> list[str]:
    """Reciprocal Rank Fusion over multiple ranked result lists."""
    scores: dict[str, float] = {}
    for ranked in ranked_lists:
        for rank, doc in enumerate(ranked, start=1):
            scores[doc] = scores.get(doc, 0.0) + 1.0 / (rrf_k + rank)
    return sorted(scores, key=scores.get, reverse=True)[:k]
```

Measured result

Strategy	MRR	Recall@5
Hybrid $\alpha=0.7$	0.3075	0.2667
Hybrid RRF	0.2867	0.2667
Hybrid RRF + Rerank	0.3625	0.3333

On the 600-paper corpus, alpha-weighted hybrid narrowly beats vanilla RRF (MRR 0.308 vs 0.287). However, RRF shines when combined with a cross-encoder reranker: the +26% MRR gain from RRF $\rightarrow$ RRF+Rerank is larger than the gain from alpha $\rightarrow$ RRF. In a production pipeline, RRF is the better fusion choice because it is score-calibration-free and generalises more predictably across corpus updates.

Improvement 5 — CRAG: 3-Tier $\rightarrow$ 2-Tier Grading Threshold**What was wrong**

The original CRAG implementation used a 3-tier relevance judgement from the LLM judge:

```
"good"      → keep the document, proceed to generate
"ambiguous" → trigger web search anyway (conservative)
"bad"       → trigger web search
```

The "ambiguous" tier caused two problems. First, the LLM often returned it for documents that were *weakly but genuinely* relevant — an abstract about transformer attention was graded "ambiguous" when the query was about self-attention, even though the document would support a reasonable answer. This triggered unnecessary web searches.

Second, parsing three tiers reliably from an LLM response (especially local models) required more fragile JSON handling. When the model returned "Ambiguous" (capital A) or "uncertain" the JSON parser failed silently and defaulted to triggering web search.

The fix

Collapse to a 2-tier system: "good" or "bad". No middle ground.

Before (prompt for 3-tier):

```
GRADE_PROMPT = """You are grading whether a retrieved document is relevant to a query.

Query: {query}
Document: {document}

Respond with JSON: {"relevance": "good" | "ambiguous" | "bad"}
Explain your reasoning in 1 sentence."""
```

Before (parsing 3 tiers):

```
def grade_document(response: str) -> str:
    data = json.loads(response)
    return data["relevance"]          # "good", "ambiguous", or "bad"

# In the graph logic:
if grade == "good":
    keep_docs.append(doc)
elif grade == "ambiguous":
    trigger_web_search = True        # conservative - often wrong
else:
    trigger_web_search = True
```

After (prompt for 2-tier):

```
GRADE_PROMPT = """You are grading whether a retrieved document is relevant to a query.

Query: {query}
Document: {document}

Respond ONLY with valid JSON: {"relevance": "good"} or {"relevance": "bad"}
A document is "good" if it contains information that could help answer the query,
even partially. Only return "bad" if the document is clearly off-topic."""
```

After (parsing 2 tiers):

```
def grade_document(response: str) -> str:
    try:
        data = json.loads(response)
        grade = data.get("relevance", "bad").lower().strip()
        return "good" if grade == "good" else "bad"
    except json.JSONDecodeError:
        return "bad"  # fail safe - treat parse failure as bad

# In the graph logic:
if grade == "good":
    keep_docs.append(doc)
else:
    trigger_web_search = True
```

Measured result

Metric	Before (3-tier)	After (2-tier)
Web search triggered	1 / 5 (20%)	0 / 10 (0%)
Faithful answers	3 / 5 (60%)	7 / 10 (70%)

The zero web-fallback rate on the 10-query eval confirms that the 2-tier threshold is less conservative. Faithfulness improved from 60% to 70% — partly because the agent now uses more of its retrieved context instead of discarding it as "ambiguous", and partly because the larger corpus means the kept context is higher quality.

When 3 tiers are appropriate

If your corpus is known to be sparse and you genuinely want aggressive web fallback, the 3-tier system is a defensible choice. The 2-tier simplification is the right call here because the expanded corpus made "ambiguous" documents almost always useful in practice.

Reading the Numbers Honestly

The retrieval metrics in this project tell two different stories depending on which row of the table you are reading. The old 5-query numbers look impressive. The new 20-query numbers look disappointing. Understanding *why* they differ is more valuable than either set of numbers in isolation — it is the core lesson of applied evaluation.

Why the Old 5-Query Numbers Are Misleading

The initial evaluation produced these results:

Strategy	Recall@5	Precision@5	MRR
Dense	0.5333	0.2400	0.4167
BM25	0.5333	0.2400	0.6667
Hybrid $\alpha=0.7$	0.5333	0.2400	0.4167
Hybrid RRF + Rerank	0.4667	0.2000	0.5000

There are three things wrong with this picture.

Problem 1 — Five queries cannot distinguish strategies

With only 5 queries, the difference between a strategy that ranks the relevant doc at position 1 versus position 3 amounts to a single query. That single query swings MRR by 0.13. The strategies are not actually performing similarly — we simply cannot measure the difference with this sample size.

Notice that Dense, BM25, and Hybrid $\alpha=0.7$ all score *identically* on Recall@5 and Precision@5 (0.5333 / 0.2400). This is statistically implausible if the strategies are genuinely different. The real explanation: with 5 queries, all three strategies happen to retrieve the same set of relevant documents (or the same number of them), and the Recall/Precision metrics cannot separate them.

Problem 2 — Few distractors inflate precision

The 300-paper corpus is small. When 300 chunks are indexed, many queries have semantically close documents in the top 5 even by chance. On a 600-paper corpus the same query has twice as many potential distractors competing for the top-5 slots. Precision inevitably drops as corpus size grows — this is expected and correct behaviour, not a regression.

Problem 3 — Trivial ground truth

The original ground truth used exact single-keyword matching: a document is relevant if its title contains a specific phrase like "BM25 ranking". This misses:

- Synonyms ("Okapi BM25", "best match 25")
- Related papers that use the concept without naming it in the title
- Abstracts where the relevant content is in the body, not the title

Single-keyword ground truth systematically underestimates recall because it excludes relevant documents that use different vocabulary. It also means the 5 queries were cherry-picked around topics with obvious, easy-to-match ground truth — not a random sample of the queries real users would ask.

Why the New 20-Query Numbers Are Honest

The expanded evaluation shows:

Strategy	Recall@5	Precision@5	MRR
Dense	0.2500	0.1200	0.2992
BM25 (improved)	0.3667	0.1900	0.4408
Hybrid $\alpha=0.7$	0.2667	0.1300	0.3075
Hybrid RRF + Rerank	0.3333	0.1700	0.3625

These numbers look lower. They are lower. They are also more accurate.

What changed

600-paper corpus — twice as many distractors. Every relevant document now competes against twice as many irrelevant ones for the top-5 slots. Precision@5 of 0.19 for BM25 means roughly 1 in 5 retrieved chunks is relevant — which is actually excellent given the corpus density.

20 diverse queries — the queries span a broader range of topics, including ones where dense retrieval is weak (keyword-heavy technical queries) and ones where BM25 is weak (conceptual paraphrase queries). A fair eval set is not designed to make any particular strategy look good.

Multi-keyword OR ground truth — a document is now relevant if its text contains any of several synonymous phrases. This is harder to satisfy precisely because more documents qualify, but it is far more representative of real relevance than a single keyword match.

No cherry-picking — the 20 queries were selected to cover the major topics in the tutorial, not to maximise any particular metric.

The Lesson: Eval Set Design Determines What You Are Measuring

This is the most important takeaway from the entire project:

The fundamental evaluation trap

A small, easy eval set does not measure whether your system is good. It measures whether your system is overfit to that eval set.

If all three of your retrieval strategies score identically on Recall@5, you have not found a universal truth about them. You have found that your eval set cannot distinguish them.

The pattern is common in ML systems:

1. Build a prototype.
2. Write a quick eval with 5 easy test cases.
3. Iterate until the 5 easy test cases all pass.
4. Ship, and discover the system fails on real-world queries.

The 5-query eval produced MRR numbers in the 0.42–0.67 range. These numbers would suggest the system is quite capable. The 20-query eval produced MRR numbers in the 0.30–0.44 range, which more honestly reflects a system that is useful but not yet production-grade.

The difference is not that the system got worse between evaluations. The difference is that the *measurement* became honest.

When MRR Matters More Than Recall@k for RAG

Both Recall@5 and MRR are reasonable metrics for retrieval evaluation, but they measure different things and one is usually more important for RAG.

Recall@5 measures coverage

Recall@5 answers: *does the relevant document appear somewhere in the top 5?*

This is the right metric when:

- You are passing all top-k results to the LLM (the LLM can find the relevant one)

- False negatives are expensive (missing the document is worse than some noise)
- Your LLM is good at ignoring irrelevant context

MRR measures rank quality

MRR answers: *how early does the first relevant document appear?*

This is the right metric when:

- Your LLM is sensitive to position in the context window
- You are truncating the context to save tokens (only passing top-2 or top-3)
- The LLM tends to anchor on the first piece of evidence it encounters

For RAG systems in practice, **MRR is the primary metric**. Here is why:

1. **Context window budget** — passing 10 chunks to a language model is expensive. Most deployments use top-3 to top-5 chunks. If the relevant document is at rank 6, it is never seen.
2. **LLM attention bias** — language models have a well-documented recency and primacy bias. A document at rank 1 is more likely to be used than a document at rank 5 even if both are present in the context.
3. **One good document is often enough** — for factoid and summary queries, the LLM needs one high-quality, relevant chunk. Getting it at rank 1 (MRR contribution: 1.0) versus rank 5 (MRR contribution: 0.2) is a large practical difference.

Recall@k is still worth tracking: a system with MRR 0.44 but Recall@5 of 0.20 has a different failure mode (it finds the right document quickly when it finds it at all, but misses it completely on many queries) than a system with MRR 0.35 and Recall@5 of 0.45 (finds something relevant most of the time but not always first).

Summary

Claim	5-query eval verdict	20-query eval verdict
Dense and BM25 perform identically	"True" (artefact of sample size)	False — BM25 +47% MRR
MRR $\approx$ 0.50–0.67 is achievable	"True" (overfit to easy eval)	No — honest MRR is 0.30–0.44
Hybrid always beats single-stage	"Supported"	Partially — only with reranking
System is production-ready	Appears yes	Directionally yes, needs more eval

A mature ML practitioner should feel *better* about a system after the honest numbers come in, not worse — because the honest numbers are what you will actually see in production.

How To Validate

Run:

```
uv run python scripts/check_docs_facts.py
```

The script verifies:

1. Artifact files exist.
2. Numeric checks match actual JSON values (with a small tolerance).
3. Deprecated model references are not present in docs.
4. Secret-like strings are not accidentally present in documentation.

Glossary

Every technical term used in this tutorial, alphabetically sorted.

Alpha weighting — A score-fusion technique that combines two ranked result lists by computing a weighted sum of their scores: $\text{final} = \alpha \times \text{score_A} + (1-\alpha) \times \text{score_B}$. The parameter α controls how much each source contributes. $\alpha=0.7$ means 70% dense, 30% BM25. Because the two sources may produce scores on different scales, alpha weighting typically requires normalisation before fusion. In this project: used in `HybridRetriever` to blend FAISS dense scores and BM25 scores, with $\alpha=0.7$ as the default.

Agentic AI — An AI architecture where an LLM does not just respond to a single prompt but takes a sequence of actions, observes results, and decides what to do next based on intermediate outcomes. The LLM acts as a *reasoner* that drives a loop rather than a function that maps input to output. Agentic systems can use tools, call external APIs, perform web searches, and grade their own outputs. In this project: the CRAG systems in `03_agentic_rag_langgraph.ipynb` and `07_agentic_rag.ipynb` are agentic pipelines where the LLM grades retrieved documents, decides whether to search the web, generates an answer, and grades its own answer for hallucinations.

ArXiv — A free, open-access repository of preprint scientific papers, primarily in physics, mathematics, computer science, and quantitative biology. Most ML and AI research is posted here before (and sometimes instead of) formal journal publication. In this project: the current baseline uses 4,000 ML/AI abstracts from `ccdv/arxiv-summarization` (ML-filtered), with legacy 600-paper results retained for historical comparison.

Bi-encoder — A neural network architecture for information retrieval where the query and each document are encoded *independently* by the same (or separate) encoder, producing fixed-length vector representations. Similarity is then computed by a simple dot product or cosine similarity between the two vectors. Because documents can be pre-encoded, bi-encoders scale efficiently to millions of documents. The trade-off is that the query and document never attend to each other during encoding. In this project: `qwen3-embedding` is the bi-encoder used to produce 1024-dimensional vectors for every chunk and for every query.

BM25 — (Best Match 25) A probabilistic keyword-based ranking function that scores documents by how well they match a query's terms, weighted by term frequency (TF) and inverse document frequency (IDF), with length normalisation. The "25" refers to the 25th iteration of the BM series of retrieval models developed at City University London. BM25 is the standard baseline for information retrieval and is hard to beat on keyword-heavy queries. In this project: implemented via the `rank_bm25` library in `src/retriever.py`, using a custom tokeniser that splits on hyphens and slashes to handle technical ML vocabulary.

ChromaDB — An open-source, embedded vector database with a Python-first API. It stores embeddings alongside metadata and supports similarity search, filtering, and persistence to disk. ChromaDB is popular for prototypes and local development because it requires no separate server process. In this project: used in Part 4 GraphRAG as one backend variant, alongside an optional Pinecone backend.

Chunking — The process of splitting a long document into smaller, overlapping or non-overlapping segments before embedding. LLM context windows and embedding models both have token limits, so raw documents must be chunked before indexing. Chunk size is a critical hyperparameter: too small and individual chunks lose context; too large and the embedding captures too much irrelevant material. In this project: each ArXiv abstract is treated as a single chunk (abstracts are naturally short, typically 150–250 words), so no splitting is required. The chunk is the abstract.

Conditional edge — In LangGraph, an edge whose target node is determined at runtime by a function that inspects the current graph state. Unlike regular edges (which always route to the same next node), conditional edges implement branching logic — the equivalent of an `if` statement in a state machine. In this project: used in the CRAG graph to route from the `grade_documents` node to either `generate` (if relevant documents were found) or `web_search` (if all documents were graded bad).

Cosine similarity — A measure of similarity between two non-zero vectors that computes the cosine of the angle between them: $\cos(\theta) = (a \cdot b) / (\|a\| \times \|b\|)$. The result is 1.0 for identical direction (same meaning), 0.0 for perpendicular vectors (unrelated topics), and -1.0 for opposite directions. Cosine similarity is the standard metric for embedding-based retrieval because it is scale-invariant — a long document and a short document with the same meaning produce vectors of different magnitude but the same direction. In this project: `IndexFlatIP` in FAISS computes dot products, which equals cosine similarity when vectors are L2-normalised (which `qwen3-embedding` produces by default).

CRAG — (Corrective Retrieval-Augmented Generation) An agentic RAG architecture introduced by Yan et al. (2024) that adds a self-correction loop to standard RAG. The system grades each retrieved document for relevance. If all documents are graded irrelevant, it triggers a web search to supplement the corpus. After generating an answer, the system grades the answer for faithfulness and can regenerate if hallucination is detected. In this project: implemented in the legacy LangGraph track (`03_agentic_rag_langgraph.ipynb`) and extended in Part 5 CRAG (`08_crag.ipynb`), with LLM-as-judge grading for retrieval and final answers.

Cross-encoder — A neural network architecture for relevance scoring where the query and a candidate document are concatenated and processed *together* by the encoder. Unlike a bi-encoder, the query and document attend to each other during encoding, allowing the model to capture fine-grained relevance signals. Cross-encoders are significantly more accurate than bi-encoders but cannot pre-encode documents — they must run at query time for every candidate, making them too slow for first-stage retrieval over large corpora. They are used as a reranker over a small candidate set (typically the top 20–50 from first-stage retrieval). In this project: the `cross-encoder/ms-marco-MiniLM-L-6-v2` model from `sentence-transformers` is used to rerank the top-20 candidates from RRF fusion, selecting the final top-5.

Dense retrieval — A retrieval paradigm that represents both queries and documents as dense floating-point vectors (embeddings) and finds relevant documents by nearest- neighbour search in the embedding space. Dense retrieval excels at semantic similarity: it can find documents whose meaning matches the query even when they share no vocabulary. Its weakness is exact keyword matching — low-frequency technical terms that appear rarely in training data produce poorly discriminative embeddings. In this project: FAISS with `qwen3-embedding` is the dense retrieval base for the core pipeline and is reused across advanced variants.

DSPy — A framework for programming (rather than prompting) language models, using optimisers to automatically tune prompts and few-shot examples based on a downstream metric. In this project: not used, but listed in Further Reading as a natural next step for systematically optimising the CRAG prompts.

DuckDuckGo — A privacy-focused web search engine. In this project: the CRAG agent uses the `duckduckgo_search` Python library to perform web searches when the local corpus cannot answer a query. The library wraps DuckDuckGo's public API and returns organic search results as structured Python objects.

Embedding — A dense, fixed-length numerical vector that represents a piece of text in a high-dimensional space where semantic similarity corresponds to geometric proximity. Embedding models are neural networks trained to map text to vectors such that similar texts produce similar vectors. Modern embedding models produce 384 to 4096-dimensional vectors. In this project: `qwen3-embedding` (via Ollama) produces 1024-dimensional vectors for every abstract chunk and for every query at retrieval time.

FAISS — (Facebook AI Similarity Search) An open-source library by Meta AI Research for efficient similarity search and clustering of dense vectors. FAISS implements dozens of index types with different accuracy/speed/memory trade-offs. It is the standard tool for embedding-based retrieval at scale. In this project: `IndexFlatIP` (exact inner-product search) is used for tutorial-scale corpora, and the index is saved to `artifacts/faiss_index/index.bin` after Part 1 for downstream loading.

Faithfulness — A property of an LLM-generated answer: the answer is *faithful* if every claim it makes is supported by (or at least not contradicted by) the retrieved documents. An unfaithful answer introduces information that is not in the context — this is a form of hallucination. In this project: faithfulness is evaluated by the LLM-as-judge node in the CRAG graph, which checks whether the generated answer is grounded in the provided document chunks.

granite4.1 — (specifically `granite4.1:8b`) IBM's Granite 4.1 8-billion-parameter instruction-tuned language model, available through Ollama. Used as the generative LLM for producing answers from retrieved context. Granite 4.1 is a capable open-weights model that runs locally on consumer hardware. In this project: the generation node calls `ollama.chat()` with `granite4.1:8b` to produce all answers, and the same model acts as the LLM judge for document grading and hallucination detection.

Grounding — The process of anchoring an LLM's response to specific, verifiable source material. A grounded answer refers to and is consistent with the retrieved documents. Grounding is what RAG buys over pure LLM generation: the model cannot fabricate facts that contradict the explicit text in the context window. In this project: grounding is enforced by always passing retrieved chunks as context in the prompt, and verified by the faithfulness grading step in the CRAG agent.

Hallucination — A generated statement that is factually incorrect, fabricated, or not supported by the provided context. Hallucination arises because LLMs are trained to predict plausible next tokens, not to verify factual accuracy. Hallucination is not random noise — it tends to produce confident, internally consistent, plausible-sounding text, which makes it hard to detect without a reference to check against. In this project: the CRAG agent includes a hallucination-detection step where the LLM judge reads the generated answer alongside the source chunks and flags answers that introduce unsupported claims.

Hybrid search — A retrieval strategy that combines results from multiple retrieval systems (typically dense and sparse) to compensate for the weaknesses of each. Dense retrieval handles semantic paraphrase; sparse retrieval handles exact keyword matching. Their combination typically outperforms either alone on diverse query sets. Fusion can be done by score weighting (alpha blend) or by rank fusion (RRF). In this project: hybrid retrieval is the core contribution of Part 2, combining FAISS dense search and BM25 sparse search.

IDF — (Inverse Document Frequency) A component of BM25 and TF-IDF scoring that measures how rare a term is across the entire corpus. IDF for term `t` is $\log((N - df_t + 0.5) / (df_t + 0.5))$ where `N` is the total number of documents and `df_t` is the number of documents containing `t`. Common words ("the", "is", "of") have low IDF; rare technical terms ("GraphSAGE", "CRAG", "LoRA") have high IDF. In BM25, high-IDF terms contribute much more to the relevance score than low-IDF terms. In this project: IDF is computed automatically by `rank_bm25` over the active corpus used for the run (legacy 600 or current 4,000 baseline).

IndexFlatIP — The specific FAISS index type used in this project. "Flat" means the index stores all vectors in a flat array and performs an exhaustive (exact) search — no approximation. "IP" stands for inner product, which equals cosine similarity when vectors are L2-normalised. The trade-off: exact accuracy but $O(n)$ search time. For 4,000 documents this is still practical for exact tutorial-scale retrieval; for millions of documents you would switch to an approximate index like `IndexIVFFlat` or `IndexHNSWFlat`. In this project: `IndexFlatIP` is built in `01_naive_rag.ipynb` and saved to `artifacts/faiss_index/index.bin`.

LangGraph — A library built on top of LangChain that enables the construction of stateful, multi-step agent workflows as directed graphs. Nodes are Python functions that read from and write to a shared state dictionary. Edges define the control flow between nodes, with conditional edges enabling runtime branching. LangGraph compiles the graph before execution (producing a `CompiledStateGraph`) and manages state persistence across steps. In this project: the CRAG state machine in Part 3 is implemented as a LangGraph graph with nodes for retrieval, grading, web search, generation, and hallucination checking.

LLM-as-judge — A technique where a language model evaluates the output of another language model (or its own output). The judge LLM is given an evaluation rubric, the input, and the output to assess, and returns a structured score or label. LLM-as-judge is widely used in RAG evaluation because human annotation is slow and expensive. Its weakness is that the judge inherits the LLM's biases — it may prefer longer answers or authoritative-sounding language regardless of correctness. In this project: the same `granite4.1:8b` model acts as judge for document relevance grading and answer faithfulness checking in the CRAG agent.

LoRA — (Low-Rank Adaptation) A parameter-efficient fine-tuning technique that injects small trainable rank-decomposition matrices into the weight matrices of a frozen pre-trained model. LoRA dramatically reduces the number of trainable parameters (typically by 10,000×) and thus GPU memory requirements during fine-tuning. In this project: LoRA appears as a topic in the ArXiv corpus (several papers on LoRA/QLoRA are indexed), and "How does LoRA reduce memory consumption?" is one of the evaluation queries.

MTEB — (Massive Text Embedding Benchmark) A comprehensive benchmark for evaluating text embedding models across dozens of tasks including retrieval, clustering, classification, and semantic textual similarity. MTEB is the standard reference for comparing embedding models. Higher MTEB retrieval score generally predicts better RAG performance. In this project: `qwen3-embedding` was selected partly based on its strong MTEB performance relative to its size, making it suitable for local deployment.

MRR — (Mean Reciprocal Rank) An evaluation metric for ranked retrieval systems. For each query, the reciprocal rank is $1 / \text{rank}$ where `rank` is the position of the first relevant document in the result list. MRR is the average of these reciprocal ranks across all queries. A system that always returns the relevant document at rank 1 has $\text{MRR} = 1.0$; one that always puts it at rank 5 has $\text{MRR} = 0.2$. MRR is the primary metric in this project because RAG performance depends on surfacing at least one relevant document quickly. In this project: MRR is computed in `src/evaluator.py` over the 20- query evaluation set.

MS MARCO — (Microsoft MACHine Reading COMprehension) A large-scale dataset of real Bing search queries paired with passages from web documents, used for training and evaluating information retrieval models. MS MARCO is the dominant training set for cross-encoder rerankers. In this project: `cross-encoder/ms-marco-MiniLM-L-6-v2` is a reranker trained on MS MARCO, used to rerank the top-20 RRF candidates.

Node — In LangGraph, a node is a Python function (or callable) that takes the current graph state as input, performs some work, and returns a (partial) state update. Nodes are the "units of computation" in the graph — each does one conceptually distinct thing: retrieve, grade, search, generate, or check. In this project: the CRAG graph has five nodes: `retrieve`, `grade_documents`, `web_search`, `generate`, and `grade_generation`.

Ollama — A tool for running large language models locally on consumer hardware. Ollama handles model downloading, quantisation, and serving behind a REST API that mirrors the OpenAI SDK interface. It supports dozens of open-weight models including Llama, Mistral, Qwen, Granite, and specialised embedding models. In this project: Ollama serves both the `qwen3-embedding` embedding model and the `granite4.1:8b` generation/judge model. All inference is local — no cloud API keys required.

Pinecone — A fully managed cloud vector database service. Pinecone handles indexing, storage, and similarity search at scale without infrastructure management. It supports metadata filtering, namespaces, and multiple index types (serverless and pod-based). In this project: used as an optional backend in Part 4 GraphRAG. The core baseline remains runnable locally without Pinecone.

Precision@k — The fraction of the top-k retrieved documents that are relevant: $\text{Precision@k} = (\text{relevant documents in top } k) / k$. Unlike Recall@k, Precision@k measures *efficiency* — how much noise is in your results. A system with Precision@5 = 0.40 means on average 2 of the top 5 results are relevant. In this project: Precision@5 is reported alongside Recall@5 in the full benchmark table, with the best score of 0.19 (BM25) on the 20-query honest eval.

qwen3-embedding — Alibaba's Qwen3 embedding model, available in various sizes. It produces 1024-dimensional L2-normalised vectors and achieves strong results on the MTEB benchmark. The model is designed for retrieval tasks and multilingual text. In this project: `qwen3-embedding` (the base variant) runs via Ollama and embeds all 600 paper chunks during the indexing step in `01_naive_rag.ipynb`. The same model embeds every query at retrieval time.

RAGAS — A framework for evaluating RAG pipelines using automatic metrics including faithfulness, answer relevance, context precision, and context recall. RAGAS uses LLM-as-judge internally to compute each metric. In this project: not used directly, but listed in Further Reading as the recommended next step for a more rigorous automated eval.

RAG — (Retrieval-Augmented Generation) An architecture that enhances LLM-generated responses by first retrieving relevant documents from an external knowledge base and providing them as context in the prompt. RAG addresses two fundamental LLM limitations: hallucination (the model invents facts it does not know) and knowledge cutoff (the model was trained on data up to a fixed date). In this project: RAG is the central subject of the entire tutorial, progressing from a naive one-stage pipeline (Part 1) through advanced retrieval techniques (Part 2) to an agentic self-correcting loop (Part 3).

Recall@k — The fraction of all relevant documents that appear in the top-k results: $\text{Recall@k} = (\text{relevant documents in top k}) / (\text{total relevant documents})$. Recall@k measures *coverage* — does the system find something useful within k results? A system with Recall@5 = 0.37 surfaces 37% of the relevant documents in the top 5 positions. In this project: Recall@5 is computed in `src/evaluator.py`. The best result on the honest 20-query eval is 0.3667 from BM25.

Reranking — A two-stage retrieval pattern where a fast first-stage retriever (dense or sparse) produces a large candidate set (e.g., top 20), and a slower but more accurate second-stage model (cross-encoder) rescores and reorders the candidates to produce the final top-k. Reranking decouples scale (handled by first-stage) from accuracy (handled by second-stage). In this project: `cross-encoder/ms-marco-MiniLM-L-6-v2` reranks the top-20 results from RRF fusion, improving MRR from 0.2867 to 0.3625 (+26%).

RRF — (Reciprocal Rank Fusion) A rank fusion algorithm that combines multiple ranked result lists without requiring score normalisation. $\text{RRF_score}(d) = \sum 1/(k + \text{rank}_r(d))$ where the sum is over all ranking systems and $k=60$ is a stability constant. Documents that appear high in multiple lists get the highest combined scores. RRF is parameter-free, robust to score distribution shifts, and scales easily to more than two retrieval systems. In this project: `rff_retrieve()` in `src/retriever.py` fuses FAISS dense rankings and BM25 rankings before the optional reranking step.

Self-querying — A RAG technique where the LLM rewrites or decomposes the user's question before retrieval — for example, extracting structured metadata filters or breaking a complex multi-hop question into sub-queries. In this project: not implemented, but listed in Further Reading as a recommended extension.

Sparse retrieval — A retrieval paradigm that represents documents as sparse high-dimensional vectors where each dimension corresponds to a vocabulary term and the value is a TF-IDF or BM25 weight. Most dimensions are zero (hence "sparse"). Sparse retrieval performs exact vocabulary matching and is highly effective for keyword-heavy queries. Its weakness is vocabulary mismatch: if the query uses a synonym not present in the document, the document is not found. In this project: BM25 is the sparse retrieval component, implemented via `rank_bm25`.

State machine — A computational model consisting of a finite set of states, a set of transitions between states triggered by events or conditions, and an initial state. At any point in time the machine is in exactly one state. Agentic LLM pipelines are naturally modelled as state machines because the agent must decide at each step which action to take based on current observations. In this project: the CRAG pipeline is a state machine where the state includes the query, retrieved documents, grades, web results, and the generated answer. LangGraph is the framework used to define and execute this state machine.

TF-IDF — (Term Frequency — Inverse Document Frequency) A classical text-weighting scheme that scores how important a term is to a document within a corpus. TF (term frequency) measures how often the term appears in the document. IDF measures how rare the term is across the corpus. Their product gives terms that are both frequent in the document and rare overall — the most discriminative terms. BM25 is a more sophisticated probabilistic extension of TF-IDF with better handling of document length and term saturation. In this project: BM25 (via `rank_bm25`) uses TF-IDF-style weighting internally; TF-IDF itself is not used directly.

uv — A fast Python package manager and project management tool written in Rust. `uv` replaces `pip`, `venv`, `pip-tools`, and `pyenv` with a unified, significantly faster interface. It resolves dependencies in milliseconds and creates reproducible lockfiles. In this project: the entire project uses `uv` for environment setup and dependency management. The `requirements.txt` lists top-level dependencies; `uv pip install -r requirements.txt` installs them into a `.venv` created with `uv venv`.

Vector database — A database specialised for storing, indexing, and querying embedding vectors. Unlike relational databases (optimised for exact matches and joins), vector databases are optimised for approximate nearest-neighbour (ANN) search in high-dimensional spaces. They typically support metadata filtering alongside vector search. Examples include FAISS (library, not a server), ChromaDB, Pinecone, Weaviate, and Qdrant. In this project: FAISS (`IndexFlatIP`) is used as a vector index (exact search, no server).

src/ingest.py — Data Loading and FAISS Indexing

Source: [src/ingest.py](#)

This module owns the build-time ingestion pipeline:

1. load papers
2. chunk documents
3. embed chunks with Ollama
4. build FAISS index
5. save/load index artifacts

It is used by notebook 01 for index creation and by downstream notebooks for index loading.

Key constants

```
EMBED_MODEL_PRIMARY = "qwen3-embedding:4b"
EMBED_MODEL_LITE = "qwen3-embedding:0.6b"
TARGET_CATEGORIES = ["cs.CL", "cs.AI", "cs.LG"]
DEFAULT_CHUNK_SIZE = 512
DEFAULT_CHUNK_OVERLAP = 64
```

`embed_texts()` and `embed_query()` default to `EMBED_MODEL_LITE` unless overridden.

Data loading

`load_arxiv_papers(n_samples, categories)`

Attempts live ArXiv retrieval first and falls back to HuggingFace when unavailable.

`load_hf_papers(n_samples, split, ml_filter, scan_multiplier)`

Loads from `ccdv/arxiv-summarization`, scans a larger slice, and keeps ML/AI-relevant rows when `ml_filter=True`.

Returns a `list[dict]` with keys:

- `id`
- `title`
- `abstract`

- `category`
 - `url`
-

Chunking

```
chunk_documents(papers, chunk_size=512, chunk_overlap=64)
```

Splits abstracts into overlapping character windows.

Returns chunk dicts including:

- `chunk_id`
 - `paper_id`
 - `title`
 - `text`
 - `chunk_idx`
 - `category`
-

Embedding

```
embed_texts(texts, model=EMBED_MODEL_LITE, batch_size=32)
```

Embeds batched text using Ollama and returns L2-normalized `float32` matrix.

```
embed_query(query, model=EMBED_MODEL_LITE)
```

Embeds one query and returns shape `(1, dim)` for FAISS search compatibility.

FAISS index

```
build_faiss_index(embeddings)
```

Builds `faiss.IndexFlatIP` over normalized embeddings.

```
save_index_and_chunks(index, chunks, base_path)
```

Persists synchronized artifacts under `base_path`:

- `artifacts/faiss_index/index.bin`

- `artifacts/faiss_index/chunks.pkl`

In this project, notebook 01 saves to `artifacts/faiss_index/`.

```
load_index_and_chunks(base_path)
```

Loads the same pair and raises `FileNotFoundError` if notebook 01 has not been executed.

Artifact contract

Downstream notebooks assume the pair below exists and remains position-aligned:

- `artifacts/faiss_index/index.bin`
- `artifacts/faiss_index/chunks.pkl`

If these files are missing, run `notebooks/01_naive_rag.ipynb` first.

src/retriever.py — Retrieval Strategies

Source: [src/retriever.py](#)

Four classes, each representing a distinct retrieval paradigm. Notebook 02 instantiates them independently and measures each one's contribution to retrieval quality.

Module-level helpers

BM25_STOP_WORDS

```
BM25_STOP_WORDS: frozenset[str] = frozenset({
    "the", "a", "an", "is", "are", "was", ...
})
```

30+ common English stop words removed during BM25 tokenisation. These words have near-zero IDF (they appear in almost every document) so removing them speeds up indexing and slightly improves BM25 precision.

_tokenise(text)

```
def _tokenise(text: str) -> list[str]:
```

The improved tokeniser used by `BM25Retriever`. Three steps:

1. `text.lower()` — case-normalise
2. `re.sub(r"[^a-z0-9]", " ", ...)` — strip all punctuation
3. Filter: remove stop words and single-character tokens

Before (old): "Transformer-based model." → ["Transformer-based", "model."]

After (new): "Transformer-based model." → ["transformer", "based", "model"]

DenseRetriever

```
class DenseRetriever:
    def __init__(self, index, chunks, embed_model=EMBED_MODEL_PRIMARY): ...
    def retrieve(self, query: str, k: int = 5) -> list[dict]: ...
```

Retrieves by cosine similarity between query and chunk embeddings. Wraps the FAISS index built in notebook 01.

`retrieve()` **returns** — top-k chunk dicts, each augmented with:

```
{"score": 0.847, "retriever": "dense", ...} # score = cosine similarity
```

- When dense wins:** paraphrase queries, semantic questions, queries with no exact vocabulary match to the corpus.
- When dense struggles:** rare technical terms, model names ("Qwen3"), dataset names ("SQuAD"), acronyms.

BM25Retriever

```
class BM25Retriever:
    def __init__(self, chunks: list[dict]): ...
    def retrieve(self, query: str, k: int = 5) -> list[dict]: ...
```

- Retrieves by BM25 keyword scoring. Builds the index at construction time from the full chunk list.
- Construction:** tokenises every chunk with `_tokenise()` and passes the result to `BM25Okapi`.

`retrieve()` **returns** — top-k chunk dicts sorted by raw BM25 score:

```
{"score": 4.21, "retriever": "bm25", ...} # raw BM25 score, NOT normalised to 0-1
```

 Score scale

BM25 scores are unbounded positive floats (typically 0–15 for our corpus). They cannot be directly compared to cosine similarity scores (0–1) without normalisation — this is why alpha fusion requires min-max normalisation.

Best result in our eval: MRR **0.441** (highest of all strategies on the 20-query eval set).

HybridRetriever

```
class HybridRetriever:
    def __init__(self, dense, bm25, alpha=0.7, fusion="alpha", rrf_k=60): ...
    def retrieve(self, query: str, k: int = 10) -> list[dict]: ...
```

Combines `DenseRetriever` and `BM25Retriever` results via one of two fusion strategies.

Parameters

Name	Default	Description
alpha	0.7	Weight for dense scores in alpha fusion (1-alpha for BM25)

Name	Default	Description
<code>fusion</code>	<code>"alpha"</code>	<code>"alpha"</code> or <code>"rrf"</code>
<code>rrf_k</code>	<code>60</code>	RRF smoothing constant (standard value from literature)

Internal strategy — `_alpha_fusion()`:

1. Collect 2k candidates from each retriever
2. Min-max normalise both score sets to [0, 1]
3. Blend: `hybrid = alpha × dense_norm + (1-alpha) × bm25_norm`
4. Sort by hybrid score, return top-k

Internal strategy — `_rrf_fusion()`:

1. Collect 2k candidates from each retriever
2. For each document: `rrf_score += 1 / (60 + rank)`
3. Sort by `rrf_score`, return top-k

Project finding: alpha fusion (MRR 0.308) slightly outperformed RRF (MRR 0.287) on this corpus because the dense score magnitude was informative — high-confidence matches had large cosine gaps that RRF discarded.

Reranker

```
class Reranker:
    def __init__(self, model_name="cross-encoder/ms-marco-MiniLM-L-6-v2"): ...
    def rerank(self, query: str, candidates: list[dict], top_k: int = 5) -> list[dict]: ...
```

Re-scores a candidate list using a cross-encoder. Intended as a second stage after

`HybridRetriever.retrieve(k=20)`.

`rerank()` steps:

1. Build `(query, chunk_text)` pairs
2. Call `CrossEncoder.predict(pairs)` — batched, CPU-only
3. Sort descending by cross-encoder logit score
4. Return top-k with `"score"` overwritten and `"retriever"` set to `"reranked"`

Latency: ~8 ms per (query, chunk) pair on CPU. For 20 candidates: ~160 ms total — acceptable for non-interactive use.

Impact in this project: RRF MRR 0.287 → RRF+Rerank MRR 0.363 (+27%).

src/evaluator.py — Evaluation Metrics

Source: [src/evaluator.py](#)

Standalone evaluation utilities used across notebook tracks. Retrieval metrics require no LLM; generation metrics call `granite4.1:8b` via Ollama as an LLM judge.

Retrieval metrics

`recall_at_k(retrieved_ids, relevant_ids, k)`

```
def recall_at_k(retrieved_ids: list[str], relevant_ids: list[str], k: int) -> float:
```

Formula: $\frac{|\text{relevant} \cap \text{top-k}|}{|\text{relevant}|}$

Returns the fraction of all relevant documents that appeared in the top-k retrieved results.

Score	Interpretation
1.0	All relevant docs found in top-k
0.5	Half of relevant docs found
0.0	No relevant docs retrieved

Example:

```
retrieved = ["2401.15884", "2312.00752", "2310.01117", "2401.00001", "2312.11111"]
relevant  = ["2401.15884", "2312.00752", "2401.99999"] # 3 relevant docs exist

recall_at_k(retrieved, relevant, k=5)
# → 2/3 = 0.667 (found 2 of 3 relevant in top-5)
```

`precision_at_k(retrieved_ids, relevant_ids, k)`

```
def precision_at_k(retrieved_ids: list[str], relevant_ids: list[str], k: int) -> float:
```

Formula: $\frac{|\text{relevant} \cap \text{top-k}|}{k}$

Returns the fraction of the top-k results that were actually relevant.

Recall vs Precision

Recall asks: "did we find everything relevant?"

Precision asks: "is everything we returned relevant?"

For RAG with k=5, precision matters more — 5 irrelevant chunks in the prompt hurt generation quality even if many relevant docs exist elsewhere.

```
mrr(queries_retrieved, queries_relevant)
```

```
def mrr(queries_retrieved: list[list[str]], queries_relevant: list[list[str]]) -> float:
```

Formula: $(1/N) \times \sum 1/\text{rank_first_relevant}$

Mean Reciprocal Rank — the average of the reciprocal rank of the first relevant document across all queries.

First relevant at rank	Reciprocal rank
1	1.000
2	0.500
3	0.333
5	0.200
Not found	0.000

Why MRR matters more than Recall@k for RAG: The LLM generator pays most attention to the first document in the context. Getting the single most relevant document to rank 1 has a greater impact on answer quality than having 4 of 5 relevant docs in the top-5.

```
compute_retrieval_metrics(retriever, eval_queries, k)
```

```
def compute_retrieval_metrics(  
    retriever,  
    eval_queries: list[dict],  
    k: int = 5,  
) -> dict:
```

Convenience wrapper that runs a full eval loop and returns a metrics dict.

eval_queries format:

```
[
  {
    "question": "How does RLHF work?",
    "relevant_ids": ["2203.02155", "2304.01852"]
  },
  ...
]
```

Returns:

```
{
  "recall@5": 0.367,
  "precision@5": 0.190,
  "mrr": 0.441,
  "k": 5,
  "n_queries": 20
}
```

Generation metrics (LLM-as-judge)

`score_faithfulness(question, context_docs, answer, model)`

```
def score_faithfulness(
    question: str,
    context_docs: list[dict],
    answer: str,
    model: str = "granite4.1:8b",
) -> dict:
```

Uses `granite4.1:8b` to judge whether every claim in `answer` is supported by `context_docs`.

Prompt pattern: *"Does this answer contain any claims not supported by the context? Return JSON {faithful: true/false, unsupported_claims: int}"*

Returns:

```
{"faithful": True, "unsupported_claims": 0}
# or
{"faithful": False, "unsupported_claims": 3}
```

LLM judge limitations

The judge is non-deterministic — the same answer can score differently across runs on borderline cases. For production use, cache grades or use a smaller dedicated classifier trained on your domain.

```
score_answer_relevance(question, answer, model)
```

```
def score_answer_relevance(question: str, answer: str, model: str = "granite4.1:8b") -> float:
```

Scores whether `answer` actually addresses `question`. Returns `0.0`, `0.5`, or `1.0`.

Faithfulness ≠ Relevance

An answer can be perfectly faithful (every claim is in the context) but irrelevant (the retrieved context was about the wrong topic). Both metrics are needed for a complete picture.

EvalResults dataclass

```
@dataclass
class EvalResults:
    experiment_name: str
    retriever_type: str
    embed_model: str
    llm_model: str
    retrieval_metrics: dict = field(default_factory=dict)
    generation_metrics: dict = field(default_factory=dict)
    notes: str = ""

    def save(self, path: Path) -> None: ...
    def load(cls, path: Path) -> "EvalResults": ...
```

Structured container for experiment results. Serialises to / from JSON via `.save()` / `.load()`.

All notebook eval results are saved under `artifacts/eval_results/`:

File	Contents
<code>artifacts/eval_results/01_naive_rag_4000.json</code>	Dense baseline metrics at 4,000-paper scale
<code>artifacts/eval_results/02_advanced_rag_4000.json</code>	Advanced retrieval metrics at 4,000-paper scale
<code>artifacts/eval_results/03_agentic_rag_4000.json</code>	Agentic CRAG metrics at 4,000-paper scale

Troubleshooting

Exact errors encountered during development, with their root cause and fix. Errors are ordered from most to least common.

ConnectionError — Ollama not running

Exact error:

```
httpx.ConnectError: [Errno 111] Connection refused
```

or

```
ollama._types.ResponseError: model not found, try pulling it first
```

or from the `ollama` Python library:

```
ConnectionError: HTTPConnectionPool(host='localhost', port=11434): Max retries exceeded
```

Cause: The Ollama daemon is not running. The `ollama` Python library connects to `localhost:11434` by default. Every embedding call and every LLM call will fail if Ollama is not up.

Fix:

```
# Start Ollama in the background
ollama serve &

# Verify it is running
curl http://localhost:11434/api/tags

# Check that the required models are pulled
ollama list
# Should show: qwen3-embedding and granite4.1:8b
```

If the models are not listed:

```
ollama pull qwen3-embedding:0.6b
ollama pull granite4.1:8b
```

`ollama.ResponseError` — Model not found

Exact error:

```
ollama._types.ResponseError: model 'granite4.1:8b' not found, try pulling it first
```

Cause: The model name in the notebook does not match the model name as stored in Ollama. This happens after a fresh install, after manually pulling a differently-tagged version, or after Ollama updates change model naming conventions.

Fix:

```
# See exact model names as Ollama knows them
ollama list

# Pull the correct model (check the exact tag)
ollama pull granite4.1:8b
ollama pull qwen3-embedding:0.6b
```

Then in the notebook, ensure the model name string matches exactly:

```
# Correct
response = ollama.chat(model="granite4.1:8b", messages=[...])

# Wrong - tag mismatch
response = ollama.chat(model="granite4.1", messages=[...]) # missing :8b
response = ollama.chat(model="granite4.1:latest", messages=[...]) # wrong tag
```

FileNotFoundError — FAISS index not found

Exact error:

```
FileNotFoundError: FAISS index not found at artifacts/faiss_index/index.bin
```

or

```
FileNotFoundError: [Errno 2] No such file or directory: 'artifacts/faiss_index/chunks.pkl'
```

Cause: Parts 2 and 3 of the tutorial load the FAISS index and chunk list that are saved at the end of Part 1 (01_naive_rag.ipynb). If you open a Part 2 or Part 3 notebook without having run Part 1 first, the `artifacts/` directory will be empty.

Fix: Run `01_naive_rag.ipynb` from top to bottom before opening any later notebook. The final cells save:

- `artifacts/faiss_index/index.bin` — the FAISS index
- `artifacts/faiss_index/chunks.pkl` — the chunk list with metadata

You only need to run Part 1 once. After that, Parts 2 and 3 can be run independently as many times as needed.

```
# Verify the artifacts exist
ls -lh artifacts/
# Should show: faiss_index/ (containing index.bin and chunks.pkl)
```

json.JSONDecodeError — grade_documents parsing failure

Exact error:

```
json.JSONDecodeError: Expecting value: line 1 column 1 (char 0)
```

or

```
json.JSONDecodeError: Extra data: line 2 column 1 (char 47)
```

Cause: The LLM judge (granite4.1:8b) returned text that is not valid JSON. This happens because:

1. The model prefixed the JSON with a reasoning preamble ("Let me think about this...")
2. The model returned markdown-fenced JSON (``json\n{...}\n``)
3. The model returned multiple JSON objects or trailing text after the JSON
4. The model returned `None` or an empty string on a very short document

Fix: Extract JSON from the response text rather than parsing it directly.

```
import json
import re

def parse_grade(response_text: str) -> str:
    """Extract relevance grade from LLM response, robust to extra text."""
    # Try direct parse first
    try:
        data = json.loads(response_text.strip())
        return data.get("relevance", "bad").lower()
    except json.JSONDecodeError:
        pass

    # Try to extract JSON object from text
    match = re.search(r'\{[^\}]+\}', response_text, re.DOTALL)
    if match:
        try:
            data = json.loads(match.group())
            return data.get("relevance", "bad").lower()
        except json.JSONDecodeError:
            pass

    # Fallback: scan for the keyword directly
    text_lower = response_text.lower()
    if '"good"' in text_lower or "'good'" in text_lower or ": good" in text_lower:
        return "good"
    return "bad"
```

Also: add explicit instructions in the prompt to not include any text before or after the JSON:

```
GRADE_PROMPT = """...
Respond ONLY with valid JSON on a single line. No explanation. No markdown.
Example: {"relevance": "good"}
"""
```

FAISS `idx = -1` sentinel — missing or corrupted results

Symptom: Retrieval returns documents with `idx=-1`, or slicing the chunk list raises `IndexError: list index out of range`.

Exact error:

```
IndexError: list index out of range
# or the returned chunk is from index -1, which is the last element
```

Cause: FAISS `IndexFlatIP.search()` returns `-1` as a sentinel value for any result slot it could not fill — this happens when `k` (number of requested results) is larger than the number of vectors in the index. If you ask for `k=5` results from an index with only 3 vectors, the last two slots contain `idx=-1` and `distance=-inf`.

```
# Naive code that breaks:
distances, indices = index.search(query_vector, k=5)
results = [chunks[i] for i in indices[0]] # crashes if i == -1
```

Fix: Filter out the `-1` sentinel before accessing the chunk list:

```
distances, indices = index.search(query_vector, k=5)
results = [chunks[i] for i in indices[0] if i != -1]
```

This is also the correct defensive pattern for production: never assume the index has at least `k` entries.

RatelimitException — DuckDuckGo web search throttled

Exact error:

```
duckduckgo_search.exceptions.RatelimitException: https://duckduckgo.com 202 Ratelimit
```

Cause: DuckDuckGo rate-limits automated search requests. The `duckduckgo_search` library wraps the public (unofficial) DuckDuckGo API. Sending more than a few queries per minute in quick succession triggers the rate limit. This most commonly occurs when running the CRAG agent on multiple queries in a loop without any delay.

Fix: Add a retry with exponential backoff, or a simple sleep between web search calls:

```

import time
from duckduckgo_search import DDGS
from duckduckgo_search.exceptions import RatelimitException

def web_search_with_retry(query: str, max_results: int = 3, retries: int = 3) -> list[str]:
    """Search DuckDuckGo with retry on rate limit."""
    for attempt in range(retries):
        try:
            with DDGS() as ddgs:
                results = list(ddgs.text(query, max_results=max_results))
                return [r["body"] for r in results if r.get("body")]
        except RatelimitException:
            wait = 2 ** attempt # 1s, 2s, 4s
            print(f"Rate limited. Waiting {wait}s before retry {attempt + 1}/{retries}...")
            time.sleep(wait)
    return [] # return empty list after all retries fail

```

In interactive notebook use, the simplest fix is to add `time.sleep(2)` before the DuckDuckGo call. The rate limit is per-IP and resets quickly.

AttributeError — CompiledStateGraph has no attribute 'graph'

Exact error:

```
AttributeError: 'CompiledStateGraph' object has no attribute 'graph'
```

Cause: LangGraph 0.4+ changed the public API for inspecting the compiled graph. Code written for LangGraph 0.3.x that accesses `compiled_graph.graph` to list nodes or visualise the graph will raise this error on 0.4+.

Affected pattern:

```

# Old code - LangGraph ≤ 0.3
app = workflow.compile()
print(app.graph.nodes.keys())      # AttributeError on 0.4+
app.graph.draw_mermaid_png(...)    # AttributeError on 0.4+

```

Fix: Use `graph_builder.nodes.keys()` (on the `StateGraph` before compilation) to list nodes, and use the compiled graph's own visualisation methods:

```
# List nodes - access the builder, not the compiled graph
workflow = StateGraph(GraphState)
workflow.add_node("retrieve", retrieve)
# ...

print(workflow.nodes.keys())          # works on the builder

# Compile
app = workflow.compile()

# Visualise - use the compiled graph's method directly
png_bytes = app.get_graph().draw_mermaid_png()
with open("graph.png", "wb") as f:
    f.write(png_bytes)
```

To check your LangGraph version:

```
python -c "import langgraph; print(langgraph.__version__)"
```

If you need to support both old and new versions:

```
try:
    nodes = list(app.graph.nodes.keys())    # 0.3.x
except AttributeError:
    nodes = list(workflow.nodes.keys())     # 0.4+
```

arxiv.HTTPError 503 / 429 — ArXiv API unavailable or rate-limited

Exact error:

```
arxiv.arxiv.HTTPError: Page request resulted in HTTP 503: Service Unavailable
```

or

```
arxiv.arxiv.HTTPError: Page request resulted in HTTP 429: Too Many Requests
```

Cause: The ArXiv API is occasionally unavailable (503) or is being rate-limited (429) when too many requests are sent in a short period. This typically happens during the data collection step in `01_naive_rag.ipynb` when fetching 600 papers across multiple keyword queries.

Fix: The project includes a HuggingFace fallback. If the ArXiv API fails, the ingest script downloads a pre-built subset of ArXiv ML abstracts from the HuggingFace Hub (the `ccdv/arxiv-summarization` or similar dataset):

```

import arxiv
import time

def fetch_arxiv_with_fallback(queries: list[str], max_per_query: int = 60) -> list[dict]:
    papers = []
    for query in queries:
        try:
            search = arxiv.Search(query=query, max_results=max_per_query)
            for result in search.results():
                papers.append({
                    "title": result.title,
                    "abstract": result.summary,
                    "arxiv_id": result.entry_id,
                })
            time.sleep(3) # be polite to the API
        except arxiv.HTTPError as e:
            print(f"ArXiv API error for '{query}': {e}. Using HuggingFace fallback.")
            papers.extend(_load_huggingface_fallback())
            break
    return papers

def _load_huggingface_fallback() -> list[dict]:
    from datasets import load_dataset
    ds = load_dataset("ccdv/arxiv-summarization", split="train", streaming=True)
    return [
        {"title": row["section_names"], "abstract": row["abstract"], "arxiv_id": "hf-fallback"}
        for _, row in zip(range(600), ds)
    ]

```

For 503 errors specifically, adding `time.sleep(10)` between query batches is usually sufficient. The ArXiv API allows ~3 requests per second but returns 503 under load.

General debugging tips

Check Ollama model names exactly:

```

ollama list
# Copy-paste the model name from this output - do not retype it

```

Verify FAISS index is not empty:

```

import faiss, pickle
index = faiss.read_index("artifacts/faiss_index/index.bin")
print(f"Index has {index.ntotal} vectors") # should be > 0
with open("artifacts/faiss_index/chunks.pkl", "rb") as f:
    chunks = pickle.load(f)
print(f"Chunks list has {len(chunks)} entries") # should match index.ntotal

```

Test Ollama embedding directly:

```
import ollama
response = ollama.embeddings(model="qwen3-embedding:0.6b", prompt="test query")
print(len(response["embedding"])) # should print 1024
```

Test Ollama generation directly:

```
import ollama
response = ollama.chat(
    model="granite4.1:8b",
    messages=[{"role": "user", "content": "Say 'hello'."}]
)
print(response["message"]["content"])
```

Further Reading

Foundational papers, benchmark datasets, and next-step projects for going deeper on every major topic in this tutorial.

Foundational Papers

CRAG — Corrective Retrieval-Augmented Generation

Yan, S., Gu, J., Zhu, Y., & Ling, Z. (2024). *Corrective Retrieval Augmented Generation*. arXiv:2401.15884.

The paper that introduced the CRAG architecture implemented in Part 3 of this tutorial. Key contributions: the relevance grading step that evaluates each retrieved document before generation, the web search fallback for queries the corpus cannot answer, and the knowledge refinement step that strips irrelevant passages from kept documents. The paper uses a different implementation (GPT-3.5, Bing search, a fine-tuned retrieval evaluator) but the core architecture maps directly to the LangGraph implementation here.

- [arXiv:2401.15884](https://arxiv.org/abs/2401.15884)
-

RAG — Retrieval-Augmented Generation (original)

Lewis, P., Perez, E., Piktus, A., Petroni, F., Karpukhin, V., Goyal, N., Küttler, H., Lewis, M., Yih, W., Rocktäschel, T., Riedel, S., & Kiela, D. (2020). *Retrieval-Augmented Generation for Knowledge-Intensive NLP Tasks*. arXiv:2005.11401. NeurIPS 2020.

The paper that coined the term RAG. Proposes combining a pre-trained retriever (DPR) with a seq2seq generator (BART) in an end-to-end trainable system. The "RAG-Sequence" and "RAG-Token" variants introduced here are the conceptual ancestors of every RAG system built since. Essential reading for understanding why the paradigm exists and what it was originally designed to solve.

-

BM25

Robertson, S., & Walker, S. (1994). *Some simple effective approximations to the 2-Poisson model for probabilistic weighted retrieval*. SIGIR 1994.

The original BM25 paper. Robertson and Walker derive the BM25 formula from first principles using a 2-Poisson model of term frequency distributions. The "25" in BM25 refers to this being the 25th parameterisation in a series of experiments. This paper is short (4 pages) and worth reading to understand why the saturation function and length normalisation terms in BM25 take the specific forms they do.

Also see the later formalisation:

Robertson, S., & Zaragoza, H. (2009). *The Probabilistic Relevance Framework: BM25 and Beyond*. Foundations and Trends in Information Retrieval, 3(4), 333–389.

MS MARCO

Bajaj, P., Campos, D., Craswell, N., Deng, L., Gao, J., Liu, X., Majumder, R., McNamara, A., Mitra, B., Nguyen, T., Rosenberg, M., Song, X., Stocker, M., Tiwary, S., & Wang, M. (2016). *MS MARCO: A Human Generated Machine Reading Comprehension Dataset*. arXiv:1611.09268.

The dataset used to train the cross-encoder reranker used in Part 2 of this tutorial (`cross-encoder/ms-marco-MiniLM-L-6-v2`). MS MARCO contains 1 million real Bing queries with relevant passages selected by human annotators from web documents. Understanding the training distribution of your reranker helps explain where it excels (web-style queries) and where it may underperform (highly technical domain-specific queries).

- [arXiv:1611.09268](#)

-

Dense Passage Retrieval (DPR)

Karpukhin, V., Oğuz, B., Min, S., Lewis, P., Wu, L., Edunov, S., Chen, D., & Yih, W. (2020). *Dense Passage Retrieval for Open-Domain Question Answering*. arXiv:2004.04906. EMNLP 2020.

The paper that established the modern bi-encoder paradigm for dense retrieval. DPR trains separate encoders for questions and passages using in-batch negatives, achieving large gains over BM25 on open-domain QA. The intuition for when dense retrieval wins over BM25 (semantic paraphrase, question-to-passage vocabulary mismatch) comes from this work.

MTEB — Massive Text Embedding Benchmark

Muennighoff, N., Tazi, N., Magne, L., & Reimers, N. (2022). *MTEB: Massive Text Embedding Benchmark*. arXiv:2210.07316. EACL 2023.

The benchmark used to evaluate and compare embedding models, including `qwen3-embedding`. MTEB covers 56 datasets across 8 task categories (retrieval, clustering, classification, reranking, summarisation, pair classification, STS, and bitext mining). Consulting the MTEB leaderboard before choosing an embedding model is the recommended practice.

Next Steps

Multi-hop RAG

Standard RAG retrieves documents in a single shot. Multi-hop RAG decomposes complex questions into sub-questions, retrieves for each, and synthesises the sub-answers. For example, "Which 2023 paper on LoRA achieved the highest GLUE score?" requires first finding LoRA papers from 2023, then finding the evaluation results within them.

Starting point: **IRCoT (Interleaving Retrieval with Chain-of-Thought)** — Trivedi et al. (2022), arXiv:2212.10509.

Self-querying retrieval

Instead of using the user's raw query for retrieval, prompt an LLM to generate a better query — one that includes synonyms, removes ambiguity, or adds metadata constraints (e.g., "papers from 2023 about transformer attention"). LangChain's `SelfQueryRetriever` provides a ready implementation.

Relevant: **Query2Doc** — Wang et al. (2023), arXiv:2303.07678.

Streaming responses

The current implementation generates a complete answer before displaying it. For interactive applications, streaming the tokens as they are generated provides a much better user experience. Ollama supports streaming via the `stream=True` parameter, and LangChain provides streaming callbacks for LangGraph nodes.

```
# Streaming with Ollama
for chunk in ollama.chat(model="granite4.1:8b", messages=[...], stream=True):
    print(chunk["message"]["content"], end="", flush=True)
```

Production deployment

The current system is a research prototype. Moving to production requires:

- **Vector database:** replace FAISS (in-memory) with Pinecone, Weaviate, or Qdrant for persistence, multi-user access, and metadata filtering.
 - **Serving:** wrap the LangGraph graph in a FastAPI endpoint.
 - **Caching:** cache embeddings and retrieval results for repeated queries.
 - **Monitoring:** log retrieval quality, answer faithfulness, and latency per query. MLflow or W&B work well for this.
 - **Index updates:** add a scheduled job that pulls new ArXiv papers and upserts their embeddings into the vector store.
-

Projects to Explore

LlamaIndex

A data framework for LLM-powered applications, with a particularly strong focus on document ingestion, chunking strategies, and index management. LlamaIndex has built-in support for hierarchical chunking, sentence-window retrieval, and document summary indexing — strategies that go beyond the simple abstract-as-chunk approach used here.

llamaindex.ai · [GitHub](#)

DSPy

A framework for *programming* (not prompting) LLMs. Instead of manually writing and tuning prompts, DSPy uses optimisers that automatically find the best prompts given a training set and a metric. Particularly useful for systematically improving CRAG-style prompts (the grading prompt, the generation prompt, the hallucination prompt) without manual iteration.

dspy.ai · [GitHub](#)

RAGAS — RAG Assessment

An evaluation framework specifically designed for RAG pipelines. RAGAS computes four metrics automatically using LLM-as-judge:

- **Faithfulness** — are the claims in the answer supported by the retrieved context?
- **Answer relevance** — does the answer actually address the question?
- **Context precision** — what fraction of the retrieved context is relevant?
- **Context recall** — does the retrieved context contain all the information needed?

RAGAS is the recommended next step for a more rigorous automated eval than the MRR/Recall@k metrics used in this tutorial.

[docs.ragas.io](#) · [GitHub](#)

Sentence Transformers

The library used under the hood for the cross-encoder reranker. The full library provides bi-encoders, cross-encoders, and dense retrieval utilities, with over 6,000 pre-trained models on HuggingFace. If you want to fine-tune your own embedding model on domain-specific text (e.g., ArXiv ML papers), Sentence Transformers provides the training infrastructure.
